

## Who Benefits from the Post-Harvest Rice Price Rise?

by

Leon A. MEARS\* and Teresa L. ANDEN\*

Economists are guilty along with sociologists of perpetuating the stereotype that because the farmer lacks finance, he is forced to sell his crop before or immediately after harvest, driving prices down. With credit, he could benefit by the higher post-harvest prices. Sacay gives emphasis to this stereotype as follows: "As a result of this (production) seasonality, prices are depressed during peak production periods and high during off-season months. For a farmer to take advantage of high prices, he must postpone the sale of his products. However, since the general level of farm income is low, agricultural products have to be sold immediately after harvest unless advances on future sales such as commodity loans are obtained."<sup>1)</sup> Mabbun in his use of the stereotype brings out the additional connotation that the middleman by buying at low prices benefits at the expense of the farmer, with a windfall from high prices going somehow automatically to those who can afford to hold stocks for later sale.<sup>2)</sup> There is both truth and fallacy in this stereotype but it is only recently that studies are providing empirical evidence for distinguishing between the two.

The authors have demonstrated elsewhere that intraseasonal price fluctuations in the Philippines can be large in some years even though seasonal indices indicate small price spreads approaching the costs of holding.<sup>3)</sup> Years with large annual price spreads were found to be interspersed with years with little or even negative price movements. In India, recent studies demonstrated a similar year to year balancing in a number of rice, wheat and sorghum markets. On average over the years, prices rose seasonally

- 2) Pablo N. Mabbun, "The Role of Farmers' Cooperatives in Raising Production and Income in the Philippines," *Economic Research Journal*, September 1964, p. 99. These same inferences are expressed by E. U. Quintana, *et al*, "The Present Situation and Outlook of the Rice Marketing Facilities with Emphasis on their Implications on the present Rice Problem of the Country," in *Rice and Related Statistics*, U. P. Statistical Center (1965), pp. 215-16.
- 3) Leon Mears and Teresa Anden, "Rice Prices and Rice Price Policy," U. P. School of Economics, IEDR Discussion Paper No. 71-19, 1971. While annual retail price peaks were observed in excess of 40 percent above post-harvest retail lows, seasonal spread based on the seasonal index from 1957/8-1968/9 did not exceed 15 percent for any of the major markets. Similar wide annual spreads were found at farm levels with considerably larger spreads of the seasonal index.

sufficient to cover only storage costs and risks.<sup>4)</sup> Does this suggest that the trader assumes risks that the smaller farmer generally would be unable to assume?

There is another fine assumption involved in the above stereotype that adds further question to the conclusions drawn. This is the assumption that holding stocks either is costless or that there is zero opportunity cost of the capital tied up. But would it pay the farmer—considering the risks involved—to hold stocks for post-harvest sale if he had to pay market charges for a loan and if he considered also the other economic costs of holding such as storage, insurance, and losses?

The authors have examined rice price swings in the Philippines to distinguish truth from fallacy in the above stereotype. After explaining the methodology utilized, the market performance is evaluated in terms of the following: 1) Would the miller/trader benefit from holding palay (unhusked rice) stocks? 2) What is the farmer's situation? 3) How do the miller's and farmer's situations compare? and 4) What do these findings suggest for policy makers?

## I Methodology

Market performance is approached from the seasonal point of view by examining: (1) the probability that a farmer or trader having his own or purchased palay at harvest season would risk taking a loss if he held the palay for future sale, and (2) the profit rate that would be realized by holding such palay after harvest. These approaches are in essence an examination of the change of price and margin over time (in the period after harvest). They assume that the farmer will not hold nor will the trader decide to hold palay unless it would be expected that the costs of holding would be covered, plus some added premium (margin) to compensate for risk, at time of future sale. Thus, this assumes a rising price as long as palay is held after harvests. If consumption is inadequate to liquidate this stock before the 2nd harvest, either the balance must be disposed of by export or a favorable speculative climate must continue to exist if traders are to be induced to hold the stocks longer.

So, during the seasonal period, excellent performance would approach that expected of a competitive market. Farm and retail prices would be rising after harvest to cover holding costs but the margin between these prices in any given period would be relatively constant throughout the year.<sup>5)</sup> Prices might decline slightly sometime

4) Uma Layant Lele, "Efficiency of Jowar Marketing: A Study of Regulated Markets in Western India," unpublished Ph. D. thesis, Cornell University, 1965 and Malcolm J. Purvis, "Marketing of Foodgrains in India: An Economic Appraisal of Government Intervention," unpublished M. S. thesis, Cornell University, 1964, both as reported by John W. Mellor, *The Economics of Agricultural Development*, Cornell University Press, 1966, p. 334.

5) Whether or not the margin is absolutely constant depends on the usual custom of the trader. While he might be in the habit of an absolutely constant margin, he might also customarily expect a certain percent mark-up. Finally, he might work in between these two, increasing the margin absolutely to compensate for these costs that vary with price, such as interest, insurance, etc.

during the 2nd harvest but would then continue to rise until the new harvest period approached. Exports, if allowed, would have to be taken into account in predicting the above pattern.

To evaluate the performance, two general approaches have been used. In both, the monthly cost of holding palay has been calculated to determine the expected absolute price increase of palay required to cover these costs in a competitive market, as follows:

$$C_n = \frac{P_{r_0}}{12} (r_1 + r_n + r_i) + s$$

where:  $C_n$  = monthly cost of holding palay

$P_{r_0}$  = farm price<sup>6)</sup> (i. e. prices received by farmers) per cavan during base month, where base month is low-price month during harvest season, i. e. November for Luzon/Cabanatuan, Luzon/Manila, Southwestern Mindanao/Cotabato, Western Visayas/Iloilo, and October for Ilocos/Laoag market.

$r_1$  = rate of storage losses from insects and pests at 3% per year.

$r_n$  = insurance rate at 1% per year.

$r_i$  = interest rate, 12% per year as charged by Rural Banks.

$s$  = storage cost at  $\approx P = 0.05$ /month/cavan of palay (or  $\approx P = 0.09$ /month in terms of rice equivalent).<sup>7)</sup>

#### Approach 1-Profit from holding palay

The rate of profit has been figured in two ways. (a) Profit ( $R$ ) or ( $r$ ) is net profit at time of sale, calculated as a percentage of the palay (or rice) value-in-sale at time of acquisition. From calculations of this measure, it can be determined how long to hold palay for maximum percentage gain over original value. It would be a useful criterion for a farmer or trader if he had no alternative use for his capital. The decision rule would then be: sell when this rate of profit is expected to be the greatest. (b) Profit ( $\bar{R}$ ) ( $\bar{r}$ ) is calculated as in (a) above but converted into per annum yields. This measure would be useful to farmers and traders with alternative uses for their capital. The decision rule could be: sell when the per annum yield is expected to drop below the opportunity cost of capital.

Each of these rates of profit (or yields) were calculated for conditions facing the farmer and trader as follows:

(a<sub>1</sub>) Farmer holds palay on the farm and sells later on the farm.

(a<sub>1a</sub>) For a given year:

- 6) When a farmer holds palay in a commercial warehouse at the wholesale market,  $P_{r_0}$  is replaced by  $P_{w_0}$ , the price of palay at that market in the base month. Gains or losses in this situation are a comparison of sales after holding with those during base month, sales in both cases assumed being made in the wholesale market.
- 7) During the time of this study, millers frequently imposed a flat  $\approx P = 0.50$ /cavan storage. Where this was the practice, calculated probabilities of loss for farmers and traders would be slightly underestimated for periods shorter than 10 months.

$$R_m = \frac{P_{fm} - P_{fo} - C_{hm}}{P_{fo}} \times 100$$

Where :

$R_m$  = rate of profit (rate of return for holding including return to capital for taking risk) from holding palay to month m

$P_{fm}$  = price of palay at the farm in month m

$C_{hm}$  = cost of holding palay to month m

m = number of months after the base month

(a<sub>1b</sub>) Over a period of years :

$$r_m = \frac{\sum_{y=1}^{y=t} (P_{fm} - P_{fo} - C_{hm})_y}{\sum_{y=1}^{y=t} (P_{fo})_y} \times 100$$

where :

$r_m$  = rate of profit (rate of return for holding including return to capital for taking risk) from holding palay each year for m months and selling an equal quantity during month m during each year of the period.

t = number of years under study.

(a<sub>2</sub>) Farmer holds palay in commercial warehouse at wholesale market and sells later as palay in that market.

(a<sub>2a</sub>) For a given year :

$$R_m = \frac{P_{wm} - P_{wo} - C_{nm}}{P_{wo}} \times 100$$

where :

$P_{wm}$  = price of palay at the wholesale market in month m

$P_{wo}$  = price of palay at the wholesale market in base month

(a<sub>2b</sub>) Over a period of years :

$$r_m = \frac{\sum_{y=1}^{y=t} (P_{wm} - P_{wo} - C_{nm})_y}{\sum_{y=1}^{y=t} (P_{wo})_y} \times 100$$

(a<sub>3</sub>). "Trader" buys palay at farm in base month and sells later as rice at retail in city.

The "trader" here, and in the analysis to follow, is considered as a proxy including all those middlemen and processors who might be involved in handling the palay from the farm through its processing, and selling it at retail. Thus, the alternative open to this "trader" is to buy palay at the farm and sell it at retail in the base month or later, after milling. If rice production and milling were fully integrated, the farmer also could act as a "trader", but it is unlikely that this is the case in the Philippines except in rare instances. So, in general this "trader" will be one or a group of non-

farmers. In these calculations, it is assumed that the margin between farm and retail remains constant.<sup>8)</sup> In other words, with prices referring to similar units in all markets, profit results whenever  $P_{rm} > (P_{ro} + M_o + C_{nm}/0.55)$

where :

$P_{rm}$  = price of rice at retail in month m

$M_o$  = farm to retail margin in base month

$C_{nm}/0.55$  = cost of holding palay to month m in terms of its rice equivalent.

(This assumes a conversion rate in milling of 0.55 cavans of milled rice for each cavan of palay.)

(a<sub>3a</sub>) For a given year, then

$$R_m = \frac{P_{rm} - P_{ro} - C_{nm}/0.55}{P_{ro}} \times 100$$

where :

$R_m$  = rate of profit (rate of return for holding including return to capital for taking risk) from holding palay for m months after purchase and selling it as rice during month m

$P_{rm}$  = per cavan price of rice at retail in month m

$P_{ro}$  = per cavan price of rice at retail in the base month

(a<sub>3b</sub>) Over a period of years :

$$r_m = \frac{\sum_{y=1}^{y=t} (P_{rm} - P_{ro} - C_{nm}/0.55)_y}{\sum_{y=1}^{y=t} (P_{ro})_y} \times 100$$

where :

$r_m$  = rate of profit (rate of return for holding including return to capital for taking risk) from holding palay each year for m months after purchase and selling an equal quantity of rice during month m during each year of the period.

(b) The profit rates calculated as in (a) above can all be converted into per annum yields by multiplying the right hand side of the equations by 12/m.

### Approach 2-Probability of taking a loss from holding palay

Probability of taking a loss by holding palay for later sale as palay (or rice) has been calculated for a series of years. First, loss or gain for a particular month of each year has been determined as follows:

(a) Farmer holds palay on the farm and sells later on the farm.

8) This assumption was used based on the findings of Mahar Mangahas in his study of secular price movements where in most regions in the Philippines, farm-retail margins stayed constant when farm prices rose, see Mahar Mangahas, *et al*, *Production and Market Relationship for Rice and Corn in the Philippines*, International Rice Research Institute, Technical Bulletin 9, (1970), p. 67. A hypothesis explaining this market response is detailed by Vernon W. Ruttan, "Agricultural Product and Factor Markets in Southeast Asia," mimeographed paper presented at the Agricultural Development Council/University of Kentucky Seminar, at Lexington, Kentucky, 1967, pp. 7-ff.

$$\text{Loss if } \frac{P_{fm}}{P_{fo} + C_{nm}} < 1$$

- (b) Farmer holds palay in a commercial warehouse and sells later as palay in the wholesale market.

$$\text{Loss if } \frac{P_{wm}}{P_{wo} + C_{nm}} < 1$$

- (c) Trader buys palay at farm in base month and sells as rice at retail in the city.

$$\text{Loss if } \frac{P_{rm}}{P_{ro} + C_{nm}/0.55} < 1$$

For each market and for each assumption, the losses and gains are totalled for each month over the period of years analyzed (1957/58 to 1968/69) and the probability of loss from holding estimated as follows:

$$\begin{aligned} & \text{Probability of loss for sale in month } m \\ & = \frac{\text{No. of years with a loss in month } m}{\text{Total number of years}} \end{aligned}$$

## II Would the Miller/Trader Benefit from Holding Stocks ?

Over the years from 1957/58 to 1968/69 millers and traders would have had monthly holding costs that varied between 1.25 and 1.41 percent of palay cost. Market prices would have had to rise monthly by these percentages if the miller/trader were to avoid a loss from holding palay for later sale as milled rice.

Probabilities of loss in different regions from the trader holding palay and selling it as milled rice in later months are shown in Table 1. For example, millers in Central Luzon who purchased their palay in November and sold 6 months later in Manila, would not have been able to cover minimum holding costs 83.3 percent of the years. Their lowest probability of loss (66-2/3 percent) would have resulted if they had sold each year after holding for 11 months. If they had purchased palay in December rather than November, they generally would have had lower probabilities of loss with the optimum month of sale being the 9th month—still with a 50 percent probability of loss. For January purchases, probability of loss declined further to only 38.5 for sales in the 7th and 8th months after harvest.

Again referring to Table 1, with high probabilities of loss indicated for all markets, it is evident that favorable-price years must have been interspersed with unfavorable-price years to make possible the low seasonal price spreads of seasonal indices approaching holding cost levels. The market area showing the lowest probabilities of loss generally was the S. W. Mindanao/Cotabato region. There, probabilities of loss would have dropped to 41.7 percent if sales had always been made in either

**Table 1** Traders' Probability of Loss<sup>1)</sup> (after deducting holding costs) from Selling Equal Quantities of Rice at Retail During Each Year from 1957/8 to 1968/9, after Holding Palay for Months Indicated after Farm Gate Purchase in Month Shown<sup>2)</sup> (in percent)

Case #	Farm Region/ Retail Market	Months Held Before Selling												Month of Palay Purchase
		1	2	3	4	5	6	7	8	9	10	11	12

2) Palay, Macan ordinario and rice, Macan 2nd class except for Case 8.

3) Wagwag palay and Wagwag 1st class rice (1959/60-1968/69 only).

Sources: Basic prices: See Appendix 1.

the 5th or 6th month after purchase. But even in this market area, during 1968/69 when price movements were least satisfactory, all sales made after the 1st month would have been at prices that did not cover holding costs, see Chart 1. And, the 1.8 percent profit rate (21.4 percent on an annual yield basis) that could have been realized for that month was at least partially a payment for risk.<sup>9)</sup> In the most favorable-price year (1962/3), losses would have resulted for all sales made before the 5th month. But for sales in the 6th or 8th months, an extremely large profit would have been realized, even after deducting a portion as a risk premium.

Chart 2 illustrates the extent to which favorable-price years were offset by unfavorable ones in major trading regions. The overall average rates of profit or loss indicated would have resulted if equal holdings had been sold during the same month in all years. In the S. W. Mindanao market, losses would have accrued to any trader/miller selling before the sixth month or after the ninth. If this same selling pattern had been followed in Western Visayas or Central Luzon, traders/millers would have shown a loss no matter what month they had chosen for selling.

Seasonal spread of selected seasonal price indices are shown in Table 2. Neither these price spreads nor the profit rates shown in Chart 2 provide a basis for accurate prediction whether profits or losses will result from holding stocks during any specific year. It is probable that this unpredictability arises from highly imperfect markets, but as Mellor suggests, these imperfections probably result more from imperfect

9) See Appendices 2 to 4 for summaries of profit and yield calculations for millers/traders.

knowledge than from collusion.<sup>10)</sup>

### III What is the Farmer's Situation ?

The farmer faces a somewhat different set of alternatives. He could sell either at the farm gate or in the wholesale market with sales at harvest or later after storing palay either on the farm or in a commercial/miller's warehouse. If he obtains a commodity loan from a formal financial institution, the farmer will be obliged to store the palay in a commercial (or FaCoMa) warehouse. Under these circumstances, his costs of holding will be on the same basis as for the trader/miller, including all holding costs and averaging 1.8 percent of harvest time palay value per month over the storage period.

His probability of loss from selling an equal quantity in the Cabanatuan wholesale market in a given month each year from 1957/58-1967/68 would have been only slightly less than for the miller (see Case 4, Table 3). Only for sales in the 7th or 10th month would it have been less than 50 percent. Given the different intraseasonal price structures at farm gate over these years, the farmer's probability of loss would have been somewhat reduced if he had chosen to make all sales at the farm (Case 1) rather than in the Cabanatuan wholesale market.

It is interesting to observe that price structures were such that the S. W. Mindanao

**Table 3** Farmers' Probability of Loss<sup>1)</sup> (after deducting holding costs) from Selling Equal Quantities of Palay —at Farm Gate or Wholesale Market— During Each Year from 1957/8 to 1967/8, after Holding for Number of Months Indicated after November Harvest<sup>2)</sup> (in percent)

farmer would have had lower probabilities of loss if he had followed a strategy opposite to the optimum for the Central Luzon farmer and made his sales at the Cotabato market rather than on the farm. It is important to observe that these high loss probabilities present quite a contrast to the picture of windfall profits inferred by the stereotype.

#### IV Comparison of the Miller's and the Farmer's Situations

From the above, it is evident that there are substantial intraseasonal price fluctuations in certain years that provide the astute trader a chance for profits but this tends to be a profit from astute trading, not from the simple act of storing. And the trader must be able to take the loss if his speculation goes sour. Many less capable traders fail when they lose their gamble.<sup>11)</sup> Lacking the background of the trader, it's likely that the farmer would be less successful in his trading and it is certain that few could stand the losses that some years would bring.

It is only when the farmer considers his own funds as having zero opportunity cost or can obtain an interest-free loan that his probability of loss would reach levels that might possibly be tolerable. Case 3 on Table 3 assumes such a situation with sales made at farm gate and all storage costs except storage losses assumed away. On that rather non-economic basis (but one which might be in the minds of some farmers) the probability of loss over the 1957/58-1967/68 period dropped to zero for sales in the 7th month and were below 30 percent until the 10th month. But even under this somewhat unrealistic condition, unfavorable-price years did appear. Chart 3 shows a comparison of the rates of loss that would have arisen from sales

**Chart 3** Farmers' Rate of Profit (or Loss) (after Deducting Holding Costs) from Selling Palay in 1963/64, 1958/59 and 1966/67 after Holding Palay for Months Indicated after Farm Purchase in November at Harvest Time Expressed as a Percent of the Price of Palay in November.

11) For documentation of millers/traders who have failed, see Chesan A. Chua, "Rice Milling in the Philippines," unpublished B. A. thesis, U. P. College of Business Administration, Quezon City (1957/58), pp. 11-ff.

at farm gate in the best and worst-price years, according to whether the farmer calculated on a full or partial cost basis.<sup>12)</sup> If sales had been made in the wholesale market, rates of loss in the worst-price year would have been even larger (see Chart 3).

### V What Do These Findings Suggest for Policy Makers?

It has been demonstrated that with economic costs of holding taken into account over the period 1957/58 to 1968/69, both farmers and traders faced a high probability of loss from holding palay for sales after harvest. Profits were possible to the astute trader, but in some years even the astute trader would have lost. The average Filipino rice farmer who has less market information and trading experience would have fared worse and could not have afforded to risk the losses that accrued in adverse-price years. It was only when farmers could have financed palay holdings with own funds, with the uneconomic assumption of zero opportunity cost, that the farmers' risk of loss from holding palay dropped to relatively low levels. The stereotype was found to have no basis in fact.

Findings described above which conflict with the stereotype position should not be taken to suggest that wide price swings do not raise both economic and political problems. When rice prices rise, there is the concern for the urban poor and the small farmer who must buy rice from the market late in the season. At the farm level, the large drop in price as the market is flooded at harvest time can seriously reduce incentives to use modern high yielding inputs. And for the miller, if he cannot reasonably predict seasonal price changes, he must remain basically a trader with little concentration given to efficient processing.<sup>13)</sup> Under these conditions the incentive is weak to invest in capital intensive modern milling equipment. At least until there is strong evidence that more accurate information can be made readily available upon which to base predictions, price policy implementation tied to buffer stocks should be seriously considered. Effectively implemented, such a policy can reduce intraseasonal swings to levels close to holding costs. This will reduce the possibility even for astute traders to profit from the simple act of holding stocks after harvest. Success of millers then will be more closely related to efficient mill operations than to price speculation.

12) See Appendices 5 to 7 for summaries of rates of profit and yield to the farmer under different selling assumption.

13) Chesan A. Chua in his study of Philippine rice milling emphasizes the general findings of the authors. He reports, "profits are made only from fluctuations or changes in the price of rice. Profits of rice mills come not from the milling of rice, but from change or increase in the price of rice," *op. cit.*, p. 11.

Amelita Mañibo and Salinda Culla spent long hours in typing and carefully proofreading successive drafts. The authors also appreciate critical discussion on this problem with Randolph Barker in the early stages of this study.

#### Appendix 1 Rice Prices: Variety, Periods, Sources and Geographic Areas Covered

Variety	Period	Area	Source
Farm Prices (palay prices received by farmers, 44 kgs)			
Macan ordinario or equivalent	1957-1970, monthly	Nation, regions	(1)
Wagwag 1st class or old harvest	1959-1970, monthly	Central Luzon	(1)
Wholesale Prices (palay, 44 kgs)			
Macan ordinario or equivalent	1957-1970, monthly	Cabanatuan	(2)
Macan ordinario or equivalent	1957-1970, monthly	Cotabato	(2a)
Retail Prices (milled rice, ganta)			
Macan 2nd or equivalent	1955-1970, monthly	Manila	(2)
Macan 2nd or equivalent	1957-1970, monthly	Cotabato, Cabanatuan, Iloilo, Laoag	(3)
Wagwag 1st class	1957-1970, monthly	Manila	(2)

(1) DANR, Bureau of Agricultural Economics

(2) Bureau of Commerce, Manila

(2a) Bureau of Commerce, Cotabato Branch

(3) Central Bank, Department of Economic Research except for Cotabato from Bureau of Commerce-Cotabato Branch up to July 1966. After July 1966 from Bureau of Commerce, Manila.

**Appendix 2** Traders' Rate of Profit<sup>1)</sup> (or Loss) and Per Annum Yield<sup>2)</sup> (after deducting holding costs) from Selling Equal Quantities of Rice at Retail in City Markets During Each Year from 1957/58-1968/69, after Holding Palay for Months Indicated after Farm Gate Purchase During Low-Price Month<sup>3)</sup>

Farm Region/Retail Market	Month of Purchase	Months Held Before Selling
