Possibility Analysis and Its Applications

大阪府立大学工学部 田中 英夫 (Hideo Tanaka)
郭 沛 俊 (Peijun Guo)

1. Introduction

The theory of possibility has been proposed by Zadeh [1], where fuzzy variables are associated with possibility distributions in the same way as random variables are associated with probability distributions [2]. The possibility measure and its dual measure call the necessity measure play important roles in establishing the possibility theory [3]. Condition possibility distributions have been defined in different forms in [4,5]. In [4], the consistency among joint, conditional and marginal possibility distributions is considered. In [5], a conditional possibility is obtained as an interval.

On the other hand, Dempster [6] introduced upper and lower probabilities, which do not satisfy the additivity, and Shafer [7] has interpreted Dempster’s work as a theory of evidence. The possibility and necessity measures are special kinds of belief and plausibility measures discussed in [8]. In Dempster-Shafer Theory, the evidence is represented by the basic probability assignment, and the combination rule of evidence is discussed. The theory is applied to obtain a certainty factor in chaining syllogism as a belief interval associated with the composition of chained rules [9].

This paper studied a certain form of evidence theory by exponential possibility distributions. Because possibility distributions are obtained from an expert knowledge, a possibility distribution is regarded as a representation of evidence in this paper. A rule of combination of evidence is given similar to Dempster’s rule [6]. Also, the measures of ignorance and fuzziness of evidence are defined by a normality factor and the area of a possibility distribution, respectively. The measures of ignorance is similar to the weight of conflict by Shafer[7], and the measure of fuzziness is the same as one defined by Kaufman and Gupta [10]. Next, marginal and conditional possibilities are defined from a joint possibility distribution, and it is shown that these three definitions are well match to each other. Thus, the posterior possibility distribution is derived from the prior possibility distribution in the same form as Bayes’ formula. This fact means that an information-decision theory can be reconstructed from the viewpoint of possibility distributions. Furthermore, linear systems whose variables are defined by possibility distributions are discussed. It shows that the operations of fuzzy vectors defined by multidimensional possibility distributions are well formulated using the extension principle of Zadeh [11].

As applications of possibility analysis, possibilistic regression [12, 13] and possibility portfolio selection [14,15] are formulated in this paper. In regression analysis, it is assumed that regression models are possibilistic linear systems defined by exponential possibility distributions. Thus, the problem of possibilistic regression is to determine an exponential possibility distribution of parametric vector in a model, which reflect the scattering of the given input-output data. In other words, the spread of the given data is transformed into the possibility distribution of the parametric vector in the model.

In portfolio selection problems, it is assumed that security data have associated with possibility grades given by experts. Those data can be described as two types of exponential possibility distributions. In other words, the upper and lower possibility distributions can be identified. Thus, we propose two types of portfolio selection models based on two types of distributions.

In numerical examples of two problems mentioned above are shown in this paper to illustrate our proposed methods.

2. Possibility distribution and its properties

An exponential possibility distribution is regarded as a representation of evidence in this paper. A kind of evidence is represented by an exponential possibility distribution as

$$
\Pi_A(x) = \exp\{-(x-a)^T D_A (x-a)\},
$$

where the evidence is denoted as $A$, $a$ is a center vector and $D_A$ is a symmetrical positive definite matrix. The parametric representation of $A$ is written as follows.

$$
A = (a, D_A),
$$

It should be noted that $\Pi_A(x)$ is normal, that is, there is an $x$ such that $\Pi_A(x) = 1$. Let us assume that $A'$ is not normal. Thus, $A'$ is given as
\[ \Pi_{a}(x) = c \exp\{-(x - \alpha)^{T} D_{a}(x - \alpha)\}, \]  
(3)

where \(0 < c < 1\).

**Definition 1:** Let a measure of ignorance of \( A' \) denoted as \( I(A') \) be defined by

\[ I(A') = -\log c \]  
(4)

It can be seen from Definition 1 that the possibility distribution given by (1) has no ignorance. The possibility distributions expressed by (1) are dealt with throughout this paper. Thus, given the evidence \( A' \) expressed by (3), \( A' \) should be normalized to obtain a normal possibility \( A \) with \( I(A) \), i.e.,

\[ \Pi_{a}(x) = \Pi_{a}(x) / c; \quad I(A) = -\log c. \]  
(5)

Thus, it should be noted that the given evidence \( A' \) is denoted as \( \Pi_{a}(x) \) with \( I(A) \).

**Definition 2:** Let a measure of fuzziness of \( A \) denoted as \( H(A) \) be defined by

\[ H(A) = \int \exp\{-(x - \alpha)^{T} D_{a}(x - \alpha)\} dx \]  
(6)

The characteristic of an evidence \( A \) can be represented as

\[ \{(a_{1}, D_{a}), I(A), H(A)\} \]  
(7)

It follows from the definition (6) that

i) \( H(A) = \pi^{n/2} |D_{a}|^{1/2} \) \( \Pi_{a}(x) \),  
(8)

ii) If \( D_{a} \geq D_{b} > 0 \), \( H(A) \leq H(B) \).  
(9)

Let us define a combination rule of possibility distributions from a similar view to Dempster's rule [7].

**Definition 3:** Let \( A_{1} \oplus A_{2} \) denote the combination of possibility distributions \( A_{1} = (a_{1}, D_{1}) \) and \( A_{2} = (a_{2}, D_{2}) \). Then the combination rule is defined as,

\[ \Pi_{(A_{1} \oplus A_{2})}(x) = k \Pi_{A_{1}} \cdot \Pi_{A_{2}} \]  
(10)

where \( k \) is a normalizing factor such that

\[ \max \Pi_{(A_{1} \oplus A_{2})}(x) = 1. \]  
(11)

It is clear from Definition 1 that the measure of ignorance of \( A_{1} \oplus A_{2} \) is given by

\[ I(A_{1} \oplus A_{2}) = \log k, \]  
(12)

which is similar to the measure of conflict defined by Shafer [7]. \( I(A_{1} \oplus A_{2}) \) can be regarded as the weight of conflict between \( A_{1} \) and \( A_{2} \).

In order to obtain \( \Pi_{(A_{1} \oplus A_{2})}(x) \), we must solve the optimization problem described in the left-hand side of (11). Thus, we have

\[ x' = (D_{1} + D_{2})^{-1} (D_{1} a_{1} + D_{2} a_{2}). \]  
(13)

Substitute \( x' \) into (10), we have

\[ k \exp(-p) = 1, \]  
where

\[ p = -(D_{1} a_{1} + D_{2} a_{2})^{T} (D_{1} + D_{2})^{-1} (D_{1} a_{1} + D_{2} a_{2}) + a_{1}^{T} D_{1} a_{1} + a_{2}^{T} D_{2} a_{2} \]  
(14)

Thus, we have

\[ k = \exp(p). \]  
(15)

Substituting \( k \) into (10) yields

\[ \Pi_{A_{1} \oplus A_{2}}(x) = ((D_{1} + D_{2})^{-1} (D_{1} a_{1} + D_{2} a_{2}), (D_{1} + D_{2})), \]  
(16)

From (15), the measure of ignorance of \( A_{1} \oplus A_{2} \) can be written as

\[ I(A_{1} \oplus A_{2}) = a_{2}^{T} D_{2} a_{2} - (D_{1} a_{1} + D_{2} a_{2})^{T} (D_{1} + D_{2})^{-1} (D_{1} a_{1} + D_{2} a_{2}) \]  
(17)

In general, the possibility distribution of \( A_{1} \oplus \cdots \oplus A_{n} \) can be obtained in the following theorem.

**Theorem 1:** The combination of \( n \) possibility distributions \( A_{i}, i = 1, \ldots, n \) can be represented as the following exponential possibility distribution.
\[ A_1 \oplus \cdots \oplus A_n = ((\sum_{i=1}^{n} D_i)^{-1} (\sum_{i=1}^{n} D_i a_i), \sum_{i=1}^{n} D_i). \]

The measure of ignorance of \( A_1 \oplus \cdots \oplus A_n \) is
\[ I(A_1 \oplus \cdots \oplus A_n) = \sum_{i=1}^{n} a_i' D_i a_i - (\sum_{i=1}^{n} D_i a_i)^{'-1} (\sum_{i=1}^{n} D_i a_i). \]

The measure of fuzziness of \( A_1 \oplus \cdots \oplus A_n \) is
\[ H(A_1 \oplus \cdots \oplus A_n) = \pi^{n/2} |(\sum_{i=1}^{n} D_i)^{-1}|^{1/2}. \]

Marginal and conditional possibility distributions are defined from the given joint possibility distribution. It is shown that these definitions are well matched to each other from the viewpoint of the given joint possibility distribution.

Let an exponential joint possibility distribution on the \((n+m)\) dimensional space be
\[ \Pi_A(x, y) = \exp \left\{ -(x-a_1, y-a_2)' \begin{bmatrix} D_{11} & D_{12} \\ D_{12} & D_{22} \end{bmatrix} (x-a_1, y-a_2) \right\}, \]
where \( x \) and \( y \) are \( n \) and \( m \) dimensional vectors, respectively. \( a_1 \) and \( a_2 \) are center vectors in \( n \) and \( m \) dimensional spaces, i.e., \( X \) and \( Y \), respectively and the positive definite matrix \( D_A \) is divided into 4 matrices as written in (21).

**Definition 4:** The marginal possibility distribution on \( X \) is defined by
\[ \Pi_A(x) = \max_{y} \Pi_A(x, y). \]

The marginal possibility distribution obtained from the exponential distribution (22) can be represented by
\[ \Pi_A(x) = (a_1, D_{11} - D_{12} D_{22}^{-1} D_{12}'), \]
which is proved as follows. The maximization problem shown in (22) can be reduced to the following minimization problem:
\[ \min_{y} (x-a_1)' D_{11} (x-a_1) + 2(y-a_2)' D_{12} (x-a_1) + (y-a_2)' D_{22} (y-a_2) . \]

The optimal solution \( y^* \) of (24) is
\[ y^* = -D_{22}^{-1} D_{12}' (x-a_1) + a_2. \]

Substituting (25) into (24) yields (23).

**Definition 5:** Given the joint possibility distribution (21), the conditional distribution given by \( y \) is defined by
\[ \Pi_A(x/y) = k \exp \left\{ -(x-a_1, y-a_2)' \begin{bmatrix} D_{11} & D_{12} \\ D_{12} & D_{22} \end{bmatrix} (x-a_1, y-a_2) \right\}, \]
where \( k \) is a normalizing factor such that
\[ \max_{x} \Pi_A(x/y) = 1. \]

By solving the optimization problem (27), \( \Pi_A(x/y) \) can be written as
\[ \Pi_A(x/y) = (a_1 - D_{11}^{-1} D_{12} (y-a_2), D_{11}), \]
which is proved as follows. Consider the problem for obtaining a normalizing factor \( k \). The maximization problem (27) can be reduced to the following minimization problem:
\[ \min_{x} (x-a_1)' D_{11} (x-a_1) + 2(y-a_2)' D_{12} (x-a_1) . \]

The optimal solution of (29) is
\[ x^* = -D_{11}^{-1} D_{12} (y-a_2) + a_1. \]

By substituting \( x^* \) into (26) and setting \( \Pi_A(x^*/y) = 1 \), we have
\[ k = \exp \left\{ (y-a_2)'(D_{22} - D_{12} D_{11}^{-1} D_{12}) (y-a_2) \right\}. \]

Substituting (31) into (26) leads to (28).

In what follows, let us show that the marginal and conditional distributions derived from the joint distribution are consistent with each other.
Theorem 2: The following relation holds.
\[ \Pi_{A}(x | y) \Pi_{A}(y) = \Pi_{A}(x, y), \] (32)
where \( \Pi_{A}(x | y) \) and \( \Pi_{A}(y) \) are derived from \( \Pi_{A}(x, y) \) by Definition 4 and 5.

From Theorem 2, we know that
\[ \Pi_{A}(x | y) = \Pi_{A}(y | x) \cdot \Pi_{A}(x | y) / \Pi_{A}(y), \] (33)
which is just the same as Bayes' theorem. Suppose that \( \Pi_{A}(y | x) \) is a possibilistic information system, where \( x \) and \( y \) are associated with cause and effect, respectively. Assuming the prior possibility distribution \( \Pi_{A}(x) \), we can calculate the posterior possibility distribution \( \Pi_{A}(x | y) \) given \( y \), using (33).

Thus, we can expect to construct an information-decision problem from the viewpoint of possibility [16].

3. Possibilistic linear systems

The possibilistic linear system with exponential distributions is defined by the following extension principle. Let \( f: X \times Y \rightarrow Z \) be a vector function. Given exponential possibility distributions \( \Pi_{A}(x) \) and \( \Pi_{B}(y) \) on \( X \) and \( Y \), respectively, the possibility distribution \( \Pi_{f(A,B)}(z) \) on \( Z \) is defined as
\[ \Pi_{f(A,B)}(z) = \max_{(x,y) \in f(x,y)} \Pi_{A}(x) \cdot \Pi_{B}(y). \] (34)

Suppose that a linear vector function is given as \( y = Tx \), where \( T \) is an \( m \times n \) matrix, \( n > m \) and \( \text{rank}[T]=m \). The possibility distribution derived from an exponential possibility distribution \( \Pi_{A}(x) = (a, D_{A})_{\ell} \), is denoted as
\[ \Pi_{TA}(y) = \max_{x \in X} \exp(-(y - a)^{T}D_{A}(y - a)). \] (35)

In other words, when a fuzzy vector \( A \) is used instead of \( x \), the fuzzy output vector \( Y \) is denoted as
\[ Y = TA, \] (36)
where the possibility distribution of \( Y \) is regarded as \( \Pi_{TA}(y) \). By solving the optimization problem (35), we have
\[ \Pi_{TA}(y) = \exp(-(y - Ta)^{T}(TD_{A}^{T}T^{-1})(y - Ta)) = (Ta_{1}(TD_{A}^{T}T^{-1})_{1}). \] (37)

Suppose that
\[ z = \lambda_{1}x + \lambda_{2}y, \] (38)
where \( \lambda_{1} \) and \( \lambda_{2} \) are constants, and \( x \) and \( y \) are governed by possibility distribution \( \Pi_{A}(x) = (a_{1}, D_{A})_{e} \) and \( \Pi_{B}(y) = (a_{2}, D_{B})_{e} \), respectively. The fuzzy vector of (38) is expressed as
\[ Z = \lambda_{1}x + \lambda_{2}y = (\lambda_{1}a_{1} + \lambda_{2}a_{2}, \lambda_{1}^{2}D_{1} + \lambda_{2}^{2}D_{2})_{e}, \] (39)
whose distribution is denoted as \( \Pi_{Z}(z) \). By solving (34), \( \Pi_{Z}(z) \) can be represented as
\[ \Pi_{Z} = (\lambda_{1}a_{1} + \lambda_{2}a_{2}, \lambda_{1}^{2}D_{1} + \lambda_{2}^{2}D_{2})_{e}. \] (40)

4. Possibility linear regression

Let us define a possibility linear system as
\[ Y = A_{1}x_{1} + A_{2}x_{2} + \ldots + A_{n}x_{n} = Ax, \] (41)
where \( x \) is a real vector(input vector) and \( A = (A_{1}, A_{2}, \ldots, A_{n}) \) is a fuzzy coefficient vector defined by \( (a_{i}, D_{A}^{-1})_{e} \). The possibility distribution \( \Pi_{Y}(y) \) of (41) can be obtained as
\[ \Pi_{Y}(y) = \exp(-(y - x'_{j}a_{i})^{T}(x'_{j}D_{A}x_{j})^{-1}) = (x'_{j}a_{i}, (x'_{j}D_{A}x_{j})^{-1})_{e}. \] (42)

Given data \( (y_{i}, x_{j}), i=1,\ldots,m \), let us formulate possibility regression analysis with the following assumptions:
1) \( y_{i} \in [Y]_{h} = \{ y | \Pi_{Y}(y) \geq h \} \),
2) \( J = \sum x'_{j}D_{A}x_{j} \rightarrow \text{minimize} \) (An index of the spread of (42)),
3) \( D_{A} > 0 \).

This formulation is given as follows:
\[
\begin{align*}
\min_{D, \mathbf{a}} \quad & J = \sum x_j^T D_x x_j \\
\text{S.T.} \quad & x_j^T D_x x_j \geq (y_j - x_j^T \mathbf{a})^2 / (-\ln h_j), \quad j = 1, \ldots, m. \\
& D_x > 0.
\end{align*}
\]

The center vector \( \mathbf{a} \) is obtained by a conventional regression method and the condition \( D_x > 0 \) is replaced by a sufficient condition as follows: Given a real symmetric matrix \( [d_{ij}] \in \mathbb{R}^{m \times m} \), the sufficient condition for this matrix being positive definite can be described as

\[
d_{ii} > \sum_{j=1, j \neq i}^{m} d_{ij}, \quad (i = 1, \ldots, n).
\]

In the LP problems, \( |d_{ij}| \) will be replaced by \( d_{ij}^+ + d_{ij}^- \) because \( d_{ij}^+ + d_{ij}^- \leq d_{ij}^- - d_{ij}^- \) \( \equiv d_{ij}^- \) where \( d_{ij}^+ \geq 0 \) and \( d_{ij}^- \geq 0 \). This is a direct corollary of Gersgorin theorem.

5. Possibility portfolio selection

Given security data \( (x_i, h_i), \ i=1, \ldots, m \), where \( x_i = [x_{i1}, \ldots, x_{in}]^T \) is a vector of returns of securities \( S_i \) \((i=1, \ldots, n)\) for the \( i \)th period. The \( h_i \) is an associated possibility grade given by an expert knowledge.

Assume that \( h_i \) \((i=1, \ldots, m)\) are expressed by a possibility distribution \((\mathbf{a}, D^{\mathbf{a}})\) .

Given the data, the upper and the lower possibility distributions denoted as \( \Pi_u \) and \( \Pi_l \), respectively, are identified to satisfy \( \Pi_u(x) \geq \Pi_l(x) \) which is similar to rough sets concept.

The center vector \( \mathbf{a} \) can be approximately estimated as \( \mathbf{a} = \mathbf{x} \) whose possibility degree \( h_i = \max_{j=1, \ldots, m} h_j \) and the associated possibility degree \( h_i \) is revised to be 1. Take \( y_i = x_i - \mathbf{a} \) and denote \( D^\mathbf{a}_u \) as \( D_u \) and \( D_l \), corresponding to the upper and lower distributions, respectively. Let us identify the upper and lower possibility distributions with the following assumptions.

1. \( \Pi_u(y_i) \leq h_i, \ i = 1, \ldots, m \)
2. \( \Pi_u(y_i) \geq h_i, \ i = 1, \ldots, m \)
3. \( \Pi_u(y_i) \geq \Pi_l(y_i) \)
4. \( \Pi_u(y_1) \times \ldots \times \Pi_u(y_m) \rightarrow \max \)
5. \( \Pi_l(y_1) \times \ldots \times \Pi_l(y_m) \rightarrow \min \)

The upper and lower distributions can be obtained by the following optimization problem.

\[
\begin{align*}
\min_{D_u, D_l} \quad & \sum_{i=1}^{m} y_i^T D_u y_i - \sum_{i=1}^{m} y_i^T D_l y_i \\
\text{subject to} \quad & y_i^T D_u y_i \leq -\ln h_i, \\
& y_i^T D_l y_i \geq -\ln h_i, \ i = 1, \ldots, m, \\
& D_u - D_l \geq 0.
\end{align*}
\]

\( D_u^{-1} - D_l^{-1} \geq 0 \) is a nonlinear constraint condition. It is difficult to solve the problem (44). Principle component analysis (PCA) is used to rotate the given data \( (y_i, h_i) \) \((i=1, \ldots, m)\) to obtain a positive definite matrix easily. The data can be transformed by the linear transformation \( \mathbf{T} \). The columns of \( \mathbf{T} \) are eigenvectors of the matrix \( \Sigma = [\sigma_{ij}] \) of given data. It should be noted that \( \mathbf{T}^T \mathbf{T} = \mathbf{I} \). \( \sigma_0 \) is defined as follows:

\[
\sigma_{ij} = \frac{\sum (x_{ij} - a_i)(x_{ij} - a_i)}{\sum h_i}.
\]

It is assumed that \( \text{rank}[\mathbf{T}] = n \). Using the linear transformation, the data \( \{y_i\} \) can be transformed into \( \{z_i = \mathbf{T}^T y_i\} \). Then we have

\[
\Pi_u(z_i) = \exp\{-z_i^T \mathbf{T}^T D_u^T \mathbf{T} z_i\}.
\]
According to the feature of PCA, $T'D_A^{-1}T$ is assumed to be a diagonal matrix as follows:

$$T'D_A^{-1}T = C_A = \begin{pmatrix} c_1 & 0 \\ \vdots & \ddots \\ 0 & c_n \end{pmatrix}.$$ (48)

Denote $C_A$ as $C_\alpha$ and $C_\iota$ for the upper and the lower possibility distribution cases, respectively. The corresponding diagonal elements in $C_\alpha$ and $C_\iota$ are denoted as $c_{\alpha j}$ and $c_{\iota j}$ ($j=1,\ldots,n$), respectively. The integrated model can be rewritten as follows.

$$\begin{align*}
\min_{C_\alpha, C_\iota} & \quad \sum_{i=1}^{m} z_i'C_\alpha z_i - \sum_{i=1}^{m} z_i'C_\iota z_i \\
\text{subject to} & \quad z_i'C_\alpha z_i \geq -\ln h_i, \\
& \quad z_i'C_\iota z_i \leq -\ln h_i, \\
& \quad c_{\alpha j} \geq c_{\iota j}, \\
& \quad i=1,\ldots,m, \quad j=1,\ldots,n, \\
& \quad c_{\alpha j} \geq c_{\iota j}, \\
& \quad i=1,\ldots,m, \quad j=1,\ldots,n, \\
& \quad c_{\alpha j} \geq c_{\iota j}, \\
& \quad i=1,\ldots,m, \quad j=1,\ldots,n.
\end{align*}$$ (49)

where $c_{\alpha j} \geq c_{\iota j} \geq \epsilon > 0$ ($j=1,\ldots,n$) make $D_{\alpha} - D_{\iota}$ semi-positive definite and $D_{\alpha}$ and $D_{\iota}$ positive. Thus, we have

$$D_{\alpha} = TC_{\alpha}^{-1}T',$$
$$D_{\iota} = TC_{\iota}^{-1}T'. \quad (50)$$

**Theorem 3:** The upper and the lower possibility distribution matrices in (48) always exist.

**Theorem 4:** Assume the data $(y_i, h_i) = 1,\ldots,m,$ are governed by an exponential possibility distribution $(0, D)$. The optimal solutions of $D_{\alpha}$ and $D_{\iota}$ in (44) are $D$.

A possibility return of a portfolio $Z$ can be written as $Z = \sum_{j=1}^{n} r_j x_j$, where $r_j$ denotes the proportion of the total investment funds devoted to the security $S_j$. Thus, $Z$ is a possibility variable with the following possibility distribution:

$$\Pi_Z = \exp\{-z - r'a\}^T(r'D_x r)^{-1}\},$$ (51)

where $r'a$ is a center value and $r'D_x r$ is a spread of $Z$.

**Portfolio selection models based on upper possibility distributions ($j=u$) and on lower possibility distributions ($j=l$)**

$$\begin{align*}
\min_r & \quad r'D_x r \\
\text{subject to} & \quad r'a = \epsilon, \\
& \quad \sum_{i=1}^{m} r_i = 1, \quad (52)
\end{align*}$$

where $\epsilon$ is an expected center value of possibility return rate.

**Theorem 5:** The spread of the possibility return obtained by the lower model is not larger than the one obtained by the upper model.

The curves from upper and lower possibility models are called possibility frontiers I and II, respectively.

5. **Numerical example**

5.1 **Possibility regression**

The input-output data are shown in Table 1. The possibility linear system is

$$Y = A_1 x_1 + A_2 x_2 = Ax.$$

The center vector $x_c$ is determined by the conventional regression analysis as $x_c = (3.7885, 0.4097)'$. 

---

The content includes mathematical expressions and theorems, mainly focusing on regression analysis and possibility distribution models. The text is structured logically, with clear division into sections and subsections, making it easier to understand and follow the reasoning and conclusions.
By solving (43), the matrix is obtained as
\[
D_A^{-1} = \begin{bmatrix} 2.93537 & 0.02637 \\ 0.02637 & 0.02637 \end{bmatrix}.
\] (54)

Fig. 1 shows the contour line (h=0.5) of the obtained possibility distribution of parameters and Fig. 2 shows the possibility regression model and the given data.

5.2 Possibility portfolio selection

Let us consider the security data shown in Table 2. In order to show the concept of upper and lower possibility distributions graphically let us just consider two securities, namely, Am.T. and At&T in Table 2. The upper and lower possibility are obtained from (49) and (50) as follows:

\[
a = [0.154, 0.176],
\]

\[
D_u^{-1} = \begin{bmatrix} 0.2665 & 0.0972 \\ 0.0972 & 0.1689 \end{bmatrix}, \quad D_l^{-1} = \begin{bmatrix} 0.0313 & 0.0165 \\ 0.0165 & 0.0148 \end{bmatrix}.
\] (55)

Fig. 3 shows the upper and lower possibility distribution of these two securities with h=0.5. From (49) and (50), we can also obtain the upper and lower possibility distributions of nine securities in Table 2. Then, the possibility efficient portfolio frontiers I and II can be obtained from (52) and shown in Fig. 4.
