Possibility Data Analysis with Rough Sets Concept

大阪府立大学工学部 田中英夫 (Hideo Tanaka)
李海寬 (Haekwan Lee)
郭沛俊 (Peijun Guo)

Abstract: This paper is dealing with the upper and lower approximation models for representing the given phenomenon in a fuzzy environment as data analysis. The upper and lower approximation models can be derived from the given data with the possibility and necessity concepts, respectively. Thus, the given phenomenon can be analyzed as two approximation models which represent the upper and lower analyses for the given data. The modalities of the upper and lower models have been illustrated in regression analysis and also in the identification methods of possibility distributions. The comparison of the concepts of possibility data analysis and rough sets is shown clearly. A measure similar to the accuracy measure of rough sets is used to clarify the difference between the data structure and the assumed model.

1. Introduction

As we know, multivariate data analysis is a main tool for analyzing the uncertainty in the real world based on probability theory. Possibility data analysis is an alternative based on possibility distributions. Multivariate data analysis considers the uncertainty as probability phenomena while possibility data analysis considers that as possibility phenomena. Possibility theory based on possibility distributions has been proposed by Zadeh [1] and advanced by Dubois and Prade [2]. There are many applications of possibility theory in various fields. For example, possibility linear regression [3, 4] and possibility portfolio selection [5] have been formulated by using exponential possibility distributions on a multi-dimensional space. The theory of exponential possibility distributions has been proposed by Tanaka and Ishibuchi [6].

Based on possibilities which are more flexible than probabilities, the upper and the lower approximation models can be obtained for representing the given phenomenon. These two models can be derived from the given data with the possibility and necessity concepts, respectively. This modalities of the upper and lower models have been illustrated in interval regression analysis and also in the identification methods of possibility distributions. The upper and lower models are closely connected to the rough sets concept [7]. Pawlak [8] has introduced approximation data analysis based on rough sets. Rough sets can be described as approximate inclusion of sets and provide a systematic framework for the study of the problems arising from imprecise and insufficient knowledge. The comparison of concepts of possibility data analysis and rough sets is shown clearly in this paper. A measure similar to the accuracy measure of rough sets is used to clarify the difference between the data structure and the assumed model.

2. Upper and lower models for interval regression

Interval regression [9] is regarded as the simplest version of possibility regression analysis and thus easily applicable in many uncertain real-life phenomena. If the given output values are intervals, we can formulate two estimation models, i.e., the upper and lower approximation models based on the inclusion relations between the given interval outputs and the estimated intervals.

2.1. Two approximation models

An interval linear system can be written as

\[ Y = A_0 + A_1 x_1 + \cdots + A_n x_n = A x \]

where \( x = (1, x_1, \ldots, x_n)' \) is an input vector, \( A = (A_0, \ldots, A_n) \) is an interval coefficient vector, and \( Y \) is the
corresponding estimated interval. An interval coefficient $A_i$ is denoted as $A_i = (a_i, c_i)$ where $a_i$ is a center and $c_i$ is a radius. Thus, an interval coefficient $A_i$ can also be expressed as

$$A_i = \left\{ u \mid a_i - c_i \leq u \leq a_i + c_i \right\} = [a_i - c_i, a_i + c_i].$$  \hspace{1cm} (2)

By interval arithmetic, the regression model (1) can be expressed as

$$Y(x_j) = (a_0, c_0) + (a_i, c_i)x_{i1} + \cdots + (a_n, c_n)x_{jn} = (a^T x_j, c^T |x_j|).$$ \hspace{1cm} (3)

where $a = (a_0, \ldots, a_n)^T$ and $c = (c_0, \ldots, c_n)^T$ and $|x_j| = (1, x_{j1}, \ldots, x_{jn})^T$. Here $a^T x_j$ and $c^T |x_j|$ represent a center and a radius of the estimated interval $Y(x_j)$ respectively.

Assume that input-output data $(x_j, Y_j)$ are given as

$$(x_j, Y_j) = (1, x_{j1}, \ldots, x_{jn}, Y_j), j = 1, \ldots, p.$$ \hspace{1cm} (4)

where $x_j$ is the $j$-th input vector, $Y_j$ is the corresponding interval output that consists of a center $y_j$ and a radius $e_j$ denoted as $Y_j = (y_j, e_j)$, and $p$ is a data size. From the data set expressed by (4) we consider two approximation models

$$Y^*(x_j) = A^*_0 + A^*_1 x_{1j} + \cdots + A^*_n x_{nj}, j = 1, \ldots, p,$$ \hspace{1cm} (5)

$$Y_*(x_j) = A_0 + A_1 x_{1j} + \cdots + A_n x_{nj}, j = 1, \ldots, p,$$ \hspace{1cm} (6)

where the interval coefficients $A^*_i$ and $A_i$ are denoted as $A^*_i = (a^*_i, c^*_i)$ and $A_i = (a_i, c_i)$, respectively. The upper and lower models can be viewed as the possibility and necessity models, respectively. The upper and lower models are defined as follows. The estimated interval $Y^*(x_j)$ by the upper model always includes the observed interval $Y_j$ whereas the estimated interval $Y_*(x_j)$ by the lower model should be included in the observed interval $Y_j$. These relations can be expressed as follows:

$$Y^*(x_j) \supseteq Y_j \iff \left\{ \begin{array}{l} a^*x_j - c^* |x_j| \leq y_j - e_j, \\ y_j + e_j \leq a^*x_j + c^* |x_j| \end{array} \right\}$$ \hspace{1cm} (7)

$$Y_*(x_j) \subseteq Y_j \iff \left\{ \begin{array}{l} a^*x_j - c^* |x_j| \leq y_j - e_j, \\ a^*x_j + c^* |x_j| \leq y_j + e_j \end{array} \right\}$$ \hspace{1cm} (8)

$$Y_*(x_j) \subseteq Y_j \subseteq Y^*(x_j).$$ \hspace{1cm} (9)

The relations given by (7)-(9) are graphically shown in Figure 1.

![Figure 1. Relations among the upper, lower approximations, and the given interval.](image)

Our main concern is to obtain interval coefficients $A^*_i$ and $A_i$, $i = 0, \ldots, n$ based on the above mentioned mutual relations. The followings are LP problems to obtain two approximation models:
Upper Approximation model;
\[
\begin{align*}
\min_{a^*, c^*} & \quad J^* = \sum_{j=1}^{p} c^* x_j \\
\text{subject to} & \quad Y^*(x_j) \supseteq Y_p, \quad j = 1, \ldots, p, \\
& \quad c_i^* \geq 0, \quad i = 0, \ldots, n.
\end{align*}
\]

Lower Approximation model;
\[
\begin{align*}
\max_{a_*, c_*} & \quad J_* = \sum_{j=1}^{p} c_* x_j \\
\text{subject to} & \quad Y_*(x_j) \subseteq Y_p, \quad j = 1, \ldots, p, \\
& \quad c_i_* \geq 0, \quad i = 0, \ldots, n.
\end{align*}
\]

where the constraint conditions in (10) and (11) refer to (7) and (8), respectively.

To obtain the upper and lower approximation models simultaneously, the following unified LP problem can be considered (see Ishibuchi and Tanaka [9]):
\[
\begin{align*}
\min_{a^*, c^*, a_*, c_*} & \quad \sum_{j=1}^{p} c^* x_j - \sum_{j=1}^{p} c_* x_j \\
\text{subject to} & \quad Y^*(x_j) \supseteq Y_p, \\
& \quad Y_*(x_j) \subseteq Y_p, \quad j = 1, \ldots, p, \\
& \quad a_{ij} + c_j \leq a_i^* + c_i^*, \\
& \quad a_i^* - c_i^* \leq a_{i_0} - c_{i_0}, \\
& \quad c_i^*, c_i_* \geq 0, \quad i = 0, \ldots, n.
\end{align*}
\]

This LP problem is combining (10) and (11) in considering inclusion relations \( A_i^* \supseteq A_i^* \), \( i = 0, \ldots, n \) between the upper and lower regression coefficients. By adding \( A_i^* \supseteq A_i^* \), \( i = 0, \ldots, n \) in LP problem (12), we obtain two models satisfying \( Y^*(x_j) \supseteq Y_*(x) \) for any \( x \).

Now suppose we have data sets \( (x_{j_o}^*, y_{j_o}^*) = (1, x_{j_1}^*, \ldots, x_{m}^*, y_{j_1}^*), \quad j = 1, \ldots, p \) which satisfies a following linear system:
\[
Y^o(x) = A^o_0 + A^o_1 x_{j_1} + \ldots + A^o_n x_{j_n}, \quad j = 1, \ldots, p.
\]

Then we obtain the following equalities
\[
A^o = A^* = A_*, \quad Y^o(x) = Y^*(x) = Y_*(x)
\]

by solving the upper approximation model (10) and the lower approximation model (11) (see Tanaka et al. [3]).

Unfortunately, the lower approximation model is not always guaranteed if we fail to assume a proper regression model. In case of no solution for linear regression with the lower approximation model, we can take a following polynomial:
\[
Y = F(x) = A_0 + \sum A_j x_j + \sum A_{jk} x_j x_k + \ldots
\]

Since a polynomial such as (15) can represent any function, the center of the lower approximation model \( Y_*(x) \) can meet the center of the observed output \( Y_p \). Thus, one can obtain an optimal solution in the lower approximation model by increasing the number of terms of the polynomial (15) until a solution is found. The existence of the lower approximation model can be interpreted as the fact that the assumed model is somewhat reliable. If we find a lower model, since there always exists an optimal solution for the upper model, the measure of fitness \( \varphi \) can be introduced as
\[
\varphi = \frac{1}{p} \sum_{j=1}^{p} \frac{c_j^*}{c_j^*} \left| x_j \right|
\]
where $0 \leq \varphi \leq 1$. This measure of fitness $\varphi$ indicates how approximately the upper and lower models are assumed to the given data. It is desirable to assume regression models which give higher value of $\varphi$. If the given input-output data satisfy a linear system (13), then we can obtain the upper and the lower models which are identical. In this case the measure of fitness $\varphi$ becomes 1.

Now assuming that an analyst may consider a tolerance limit $\omega$ such that $\varphi \geq \omega$, we propose a new algorithm which gives two approximate models for the interval regression analysis.

**Algorithm obtaining two approximation models:**

Step 1: Take a linear function as regression model: 
$$ Y = A_0 + \sum A_j x_j . $$

Step 2: Solve the lower approximation model (11). If there is an optimal solution in the model (11), go to Step 4. Otherwise, go to Step 3.

Step 3: Increase the number of terms of the polynomials, i.e., 
$$ Y = A_0 + \sum A_j x_j + \sum A_{ij} x_i x_j . $$

Go to Step 2.

Step 4: Solve the unified LP problem (12) and calculate the measure of fitness $\varphi$ of the two models. If $\varphi \geq \omega$, then go to Step 5 (We already have the optimal upper model $Y^u(x)$ and the optimal lower model $Y_l(x)$ satisfying $Y^u(x) \supseteq Y_l(x)$ for any $x$). Otherwise, go to Step 3.

Step 5: End the procedure.

**2.2. A numerical example**

The data set of crisp inputs and interval outputs is shown in Table 1. The proposed algorithm is applied to obtain two approximate interval regression models under the assumption of $\omega = 0.25$ as a tolerance limit.

Using a linear regression model, we obtained the following upper and lower models

$$ Y^u(x) = (-0.6563, 2.7813) + (2.2813, 0.5938)x $$

$$ Y_l(x) = (0.8125, 0) + (1.7422, 0.0547)x $$

![Diagram of interval regression analysis](image_url)

(a) $Y = A_0 + A_1 x$ ($\varphi_r = 0.0458$)
which are depicted in Figure 2 (a) where the outer two lines represent the upper model and the inner two lines represent the lower model. But the measure of fitness is \( \varphi (=0.0458) < \omega (=0.25) \). Thus we rejected the obtained models. Therefore we increase the number of terms of the polynomials as (18). By solving the unified LP problem (12), we obtained the upper model \( \mathrm{Y}^*(x) \) and the lower model \( \mathrm{Y}_*(x) \) denoted as
\[
\begin{align*}
\mathrm{Y}^*(x) &= (3.7118, 0.8507) - (0.1958, 0.3625)x + (0.2340, 0.0368)x^2 \\
\mathrm{Y}_*(x) &= (3.3417, 0.4806) + (0.0597, 0.1347)x + (0.1972, 0)x^2
\end{align*}
\]
which are depicted in Figure 2 (b). The measure of fitness is greater than the tolerance limit, i.e., \( \varphi (=0.3281) > \omega (=0.25) \). Thus we accept (21) and (22) as optimal models which satisfy \( \mathrm{Y}^*(x) \supseteq \mathrm{Y}_*(x) \) for any \( x \).

3. Identification methods of upper and lower possibility distributions

Let us begin with the given data \((x_j, h_j), (j=1, \ldots, p)\) where \( x_j = (x_{j1}, \ldots, x_{jn}) \) is a vector and \( h_j \) is an associated possibilistic grade given by expert knowledge. Assume that \( h_j \) \((j=1, \ldots, p)\) are expressed by a possibility distribution \( A \) defined as
\[
\Pi_A(x_j) = \exp\{- (x_j - a)^T D_A^{-1} (x_j - a)\} = (a, D_A),
\]
where \( a = (a_1, \ldots, a_n) \) is a center vector and \( D_A \) is a symmetric positive definite matrix, denoted as \( D_A > 0 \).

Given the data, the problem is to determine an exponential possibility distribution of (23), i.e., a center vector \( a \) and a symmetric positive definite matrix \( D_A \). According to two different viewpoints, the upper and lower possibility distributions are introduced in this section. The upper and lower possibility distributions denoted as \( \Pi_u \) and \( \Pi_l \), respectively should be assumed to satisfy the inequality \( \Pi_u(x) \supseteq \Pi_l(x) \), \( \forall x \) with considering some similarities between our proposed methods and rough sets.

The center vector \( a \) can be approximately estimated as
\[
a = x_j \tag{24}
\]
whose \( h_j = \max_{k=1,\ldots,p} h_k \) and the associated possibility degree \( h_j \) is revised to be 1. Taking the transformation \( y_j = x_j - a \), a possibility distribution with the zero center vector is as follows:
\[
\Pi_A(y_j) = \exp\{- y_j^T D_A^{-1} y_j\} = (0, D_A),
\]
where \( D_A \) is denoted as \( D_u \) and \( D_l \) corresponding to \( \Pi_u \) and \( \Pi_l \), respectively.
3.1. Upper and lower distributions by the integrated model

The upper and lower distributions are used to reflect two kinds of distributions from the upper and lower directions.

Let us identify the upper and lower possibility distributions with the following assumptions whose meanings are illustrated in Figure 3.

1) Maximize $\Pi_{l}(y) \times \cdots \times \Pi_{l}(y)$ subject to $\Pi_{l}(y) \leq h_{j}, \ j = 1, \ldots, \ p.$ (Lower distribution)

2) Minimize $\Pi_{u}(y) \times \cdots \times \Pi_{u}(y)$ subject to $\Pi_{u}(y) \geq h_{j}, \ j = 1, \ldots, \ p.$ (Upper distribution)

3) $\Pi_{u}(y) \geq \Pi_{l}(y).$  (Relation of upper and lower distributions)

The upper and lower distributions can be simultaneously obtained by the following optimization problem.

$$
\begin{align*}
\frac{1}{y_{l}} \sum_{j=1}^{p} y_{j} D_{u}^{-1} y_{j} - \sum_{j=1}^{p} y_{j} D_{u}^{-1} y_{j} \\
\text{subject to } y_{j} D_{u}^{-1} y_{j} \leq -\ln h_{j}, \\
y_{j} D_{u}^{-1} y_{j} \geq -\ln h_{j}, \ j = 1, \ldots, \ p, \\
D_{u} - D_{l} \geq 0, \\
D_{l} \geq 0.
\end{align*}
$$

(26)

It is obvious that (26) is a nonlinear optimization problem which is difficult to be solved.

To cope with this difficulty, we will use principle component analysis (PCA) to rotate the given data by the linear transformation $T$ to obtain a positive definite matrix easily. The columns of $T$ are characteristic vectors of matrix $\Sigma = \{\sigma_{ij}\}$ of given data, where $\sigma_{ij}$ is defined by the following formulation.

$$
\sigma_{ij} = \{\sum_{k=1}^{n} (x_{i} - a)(x_{j} - a) / \sum_{k=1}^{n} h_{k}. \}
$$

(27)

Figure 3. Graphic explanation of upper and lower distributions.

Using the linear transformation, the data $\{y_{j}\}$ can be transformed into $\{z_{j} = T^{t}y_{j}\}$. Then we have

$$
\Pi_{A}(z_{j}) = \exp(-z_{j}^{t}T D_{A}^{-1} T z_{j}).
$$

(28)

According to the feature of PCA, $T D_{A}^{-1} T$ is assumed to be a diagonal matrix as follows:

$$
T D_{A}^{-1} T = C_{A} = \begin{bmatrix}
    c_{1} & 0 \\
    \vdots & \ddots \\
    0 & c_{n}
\end{bmatrix}
$$

(29)
Denote $C_A$ as $C_u$ and $C_l$ for the upper and lower possibility distribution cases, respectively. The corresponding diagonal elements in $C_u$ and $C_l$ are denoted as $c_{ui}$ and $c_{li}$, $(i = 1, \ldots, n)$, respectively. The integrated model can be rewritten as follows:

\[
\min_{z, C_u, C_l} \sum_{j=1}^{p} z_j' C_u z_j - \sum_{j=1}^{p} z_j' C_l z_j
\]

subject to \(z_j' C_u z_j \leq -\ln h_j\), \(z_j' C_l z_j \geq -\ln h_j\), \(j = 1, \ldots, p\),

\(c_{ui} \geq \epsilon\), \(c_{li} \geq c_{ui}\), \(i = 1, \ldots, n\),

where \(c_{ui} \geq c_{li} \geq \epsilon > 0\), \((i = 1, \ldots, n)\) make $D_u$ and $D_l$ positive definite, and $D_u - D_l$ semi-positive definite. Thus, we have

\[
D_u = TC_u^{-1} T', \quad D_l = TC_l^{-1} T'.
\]

Similar to regression analysis, we can define the measure of fitness $\eta$ as

\[
\eta = \frac{1}{p} \sum_{j=1}^{p} \frac{I_j(x)}{I_u(x)}.
\]

3.2. A numerical example

The data in the possibility portfolio problem are given in the following table.

From the proposed approach explained in Section 3.1, we obtained
Using the formulation (30) and (31), we obtained the two possibility distributions as shown in Figure 4 where the outer ellipse is the upper possibility distribution and the inner ellipse is the lower one for \( h = 0.5 \), respectively. From (33), we obtained \( \eta = 0.226 \).

![Figure 4](image.png)

**Figure 4.** The upper and lower possibility distributions.

### 4. Similarities between proposed models and rough sets

Let a set \( X \subseteq U \) be given. Then an upper approximation of \( X \) in \( A \) denoted as \( A^u(X) \) means the least definable set containing \( X \), and a lower approximation of \( X \) in \( A \) denoted as \( A^l(X) \) means the greatest definable set contained in \( X \). The upper approximation \( A^u(X) \) and the lower approximation \( A^l(X) \) can be defined as

\[
A^u(X) = \bigcup_{E_i \subseteq X} E_i, \quad A^l(X) = \bigcap_{E_i \subseteq X} E_i,
\]

where \( E_i \) is the \( i \)-th elementary set in \( A \). An accuracy measure of a set \( X \) in the approximation space \( A = (U, R) \) is defined as

\[
\alpha_x(X) = \frac{\text{Card}(A^u(X))}{\text{Card}(A^l(X))}
\]

where \( \text{Card}(A^u(X)) \) is the cardinality of \( A^u(X) \). When the classification \( C(U) = \{X_1, \ldots, X_n\} \) is given, the accuracy of the classification \( C(U) \) is defined as

\[
\beta_x(U) = \frac{\text{Card}(\cup A^l(X_i))}{\text{Card}(\cup A^u(X_i))}
\]

whose concept is used to define the measure of fitness in interval regression analysis and the identification methods of exponential possibility distributions. Furthermore, the upper and lower approximations of \( X \), \( A^u(X) \) and \( A^l(X) \) are corresponding to the upper and lower approximation models in regression analysis and in the identification methods of possibility distributions. Thus, we can summarize the similarities between our models and rough sets in Table 3.
5. Concluding remarks

In the foregoing research, we are going to formulate portfolio selection problems, DEA (Data Envelopment Analysis), and possibility decision problems with the upper and lower models. It is emphasized that the upper and lower models can really represent possibility phenomena which are a kind of uncertainty.
