Scope of Research

Structure and function of biocatalysts, in particular, pyridoxal enzymes and enzymes acting on xenobiotic compounds, are studied to elucidate the dynamic aspects of the fine mechanism for their catalysis in the light of recent advances in gene technology, protein engineering and crystallography. In addition, the metabolism and biofunction of sulfur, selenium, and some other trace elements are investigated. Development and application of new biomolecular functions of microorganisms are also studied to open the door to new fields of biotechnology. For example, molecular structures and functions of psychrophilic enzymes and their application are under investigation.

Probing Active-site Environment of Fluoroacetate Dehalogenase by Catalysis-Linked Inactivation with Ammonia

Fluoroacetate dehalogenase (FAc-DEX; EC 3.8.1.3) from *Moraxella* sp. B catalyzes the hydrolytic dehalogenation of fluoroacetate and other haloacetates to produce glycolate. FAc-DEX is the only enzyme that catalyzes the degradation of an aliphatic fluorinated compound by cleaving the carbon-fluorine bond, whose dissociation energy is among the highest in natural compounds. Asp105 of the enzyme acts as a nucleophile to attack the α-carbon of haloacetate to form an ester intermediate, which is subsequently hydrolyzed by a water molecule activated by His272 (Scheme 1). We found that FAc-DEX is inactivated concomitantly with defluorination of fluoroacetate by incubation with ammonia. Mass spectrometric analyses revealed that the inactivation of FAc-DEX was caused by nucleophilic attack of ammonia on the ester intermediate to convert the catalytic residue, Asp105, into an asparagine residue. The results indicates that ammonia reacted the active site of FAc-DEX without losing its nucleophilicity.

Functional characterization of Alanine racemase from *Schizosaccharomyces pombe*

Recent discovery of the physiological importance of D-amino acids has attracted much interest in the study of metabolism of D-amino acids in eucaryotic cells. We found that fission yeast, *Schizosaccharomyces pombe*, has several enzymes acting on D-amino acids (Scheme 2). We here describe one of these enzymes, alanine racemase, encoded by the alr1+ gene. We cloned the alr1+ gene in *E. coli* and purified the gene product (Alr1p) with an Mr of 41,590 to homogeneity. Alr1p contains pyridoxal 5'-phosphate as a coenzyme and catalyzes racemization of alanine. The enzyme is almost specific to alanine, but L-serine are racemized slowly at rate of 3.7 % of that of L-alanine. *S. pombe* uses D-alanine as a sole nitrogen source, but deletion of the alr1+ gene resulted in retarded growth on the same medium. *Saccharomyces cerevisiae* differs markedly from *S. pombe*: *S. cerevisiae* uses L-alanine but not D-alanine as a sole nitrogen source. Moreover, D-alanine is toxic to *S. cerevisiae*. However, heterologous expression of the alr1+ gene enabled *S. cerevisiae* to grow efficiently on D-alanine as a sole nitrogen source. The recombinant yeast was relieved from the toxicity of D-alanine.

Analysis of the three-dimensional structure of the enzyme by homology modeling showed that the active site of the enzyme is mainly composed of hydrophobic (Phe35, Tyr148, Trp151, Tyr213, and Phe273) and basic (His104, Arg106, Arg109, and His272) residues, which are considered to be essential for an ammonia molecule to retain its nucleophilicity. In a normal enzyme reaction, the hydrophobic environment is supposed to prevent hydration of the highly electronegative flurine atom of the substrate and contribute to fluorine recognition by the enzyme. Basic residues probably play a role in counterbalancing the electronegativity of the substrate.
