An Optimal Rate of the National Burden in an Aging Japan

Akira Okamoto

1. Introduction

With a population that is aging faster than any other in the world, Japan faces serious problems with its public finance, particularly when it comes to tax and social security issues. Structural reforms are urgently needed to accommodate the impending demographic change. There has recently been increased discussion about the “rate of the national burden” in Japan. When reconstructions of public finance or fiscal structural reforms were implemented in past years, one of the government’s aims was to keep the rate of the national burden below 50%. One of the main reasons for this is that, as the rate of the national burden becomes high, economic vitality is diminished.

1) Japan’s population has the highest old-age dependency ratio. However, the Republic of Korea is currently the fastest aging country in the OECD member countries.
Several recent studies, however, have suggested that the size of the welfare state has no relation to the rate of economic growth. For example, Atkinson (1999) reported that the results of econometric studies of the relationship between social transfer spending and growth rates are mixed: some find that high spending on social transfers leads to lower growth, others find the reverse, and thus that the studies of the aggregate relationship between economic performance and the size of the welfare state reviewed in his book do not yield conclusive results.

This paper aims to establish guidelines for fiscal reform in Japan’s graying society by looking at Japanese tax and social security systems through an extended life-cycle general equilibrium simulation model. Many papers have studied tax reforms using this kind of model; for instance, Auerbach and Kotlikoff (1987), Altig et al. (2001), and Ihori et al. (2005). However, these papers incorporate taxes into their models but do not take account of the fact that government expenditure enhances households’ utility. Moreover, few studies have examined an optimal rate of the national burden, taking full account of the benefits that the government provides to households.

Therefore, we explicitly consider that public services improve households’ welfare, which is the main contribution that this paper aims to make. This enables us to comprehensively evaluate the balance between benefits and burdens, and thus to investigate an optimal rate of the national burden. We explore an optimal rate of the national burden during the rapid aging of the Japanese population.

When taking account of the fact that households receive benefits coming from government spending, there are two crucial aspects. One is to what degree households put a utility weight for the benefits coming from government expenditure, compared with their private consumption. The other is to what degree the goods and services that the government provides to households take on the character of public or private goods. If government expenditure takes on the character of public goods, its benefits to households are widespread. On the other hand, if it takes on the character of private goods, its benefits to households are restricted. Because simulation results depend substantially on the parameter values that determine the above degrees, we undertake sensitivity analyses for changes in these parameter values.

This paper is organized as follows. The next section identifies the basic model employed in the simulation analysis. Section 3 explains the method of simulation analysis and the assumptions adopted. Section 4 evaluates the simulation findings and discusses policy implications. Section 5 summarizes and concludes the paper.

2. Theoretical Framework

The life-cycle growth model employed in this paper is grounded in the microeconomics of intertemporal choice, and the macroeconomics of savings and growth. The simulation model has three features. First, aggregate assets of the economy in each period consist of the assets of different generations that maximize their lifetime utility. This allows us to rigorously analyze changes in the supply
of assets caused by demographic changes. Second, assets in the capital market, where aggregate assets appear as real capital, affect the production level. Third, it is possible to estimate realistic consumption-savings profiles for the elderly, by incorporating life-length uncertainty and unintended bequests into the model.

We calibrate the simulation of the Japanese economy by employing population data estimated by the National Institute of Population and Social Security Research in 2002. The model has 75 different overlapping generations. Three types of agents are considered: households, firms, and the government. The basic structure of households is as follows.

### 2.1. Household Behavior

Households are divided into three income classes: low, medium, and high\(^2\). A single household type represents each income class. Each household has the same mortality rate and the same utility function. Unequal labor endowments, however, create different income levels. Each household appears in the economy as a decision-making unit at the age of 21 and lives to a maximum of 95. Households face an age-dependent probability of death. Let \( q_{j+1|j} \) be the conditional probability that a household of age \( j \) lives to \( j + 1 \). Then the probability of a household of age 21 surviving until age \( s \) can be expressed by

\[
ps = \prod_{j=21}^{s-1} q_{j+1|j}. 
\]

The probability \( q_{j+1|j} \) is calculated from data estimated by the National Institute of Population and Social Security Research (2002).

The utility of each household depends on the levels of consumption and the public services that the government provides to each household. There is no choice between leisure and labor supply. Each household works from age 21 to \( RE \), the retirement age. The labor supply is inelastic before retirement and zero after retirement (see the first comment in Section 4.2 for the explanation of this assumption). Each household that maximizes the expected lifetime utility makes lifetime decisions at age 21 concerning the allocation of wealth between consumption and savings. The utility function of a representative household of income class \( i \), the form of which is assumed to be time-separable, is

\[
U_i = \frac{1}{1 - \frac{1}{\gamma}} \sum_{s=21}^{95} p_s (1 + \delta)^{-(s-21)} \left\{ C_s \right\}^{1-\frac{1}{\gamma}} + \mu \left\{ \frac{G_t}{AN_t^p} \right\}^{1-\frac{1}{\gamma}},
\]

where \( C_s \) represents consumption (or expenditure) at age \( s \), \( \delta \) the adjustment coefficient for discounting the future, and \( \gamma \) is the intertemporal elasticity of substitution.

\(^2\) Okamoto (2005a) also incorporated three representative households with different earnings abilities. Altig et al. (2001) dealt with differences of lifetime earnings ability by incorporating 12 lifetime-income groups into a life-cycle model. Furthermore, Okamoto (2005b) introduced numerous representative households with continuous income distribution in each cohort.
in different years. The superscript \( i \) \((= l, m, h)\) stands for low, medium, and high-income classes, respectively.

The goods and services that the government provides to households are incorporated, with reference to Borcherding (1985). \( G_t \) is government spending on goods and services in year \( t \), \( AN_t \) the size of the households, namely, the total population at period \( t \), \( \mu \) a weight placed on the benefits coming from government expenditure (i.e., public services), and the exponent \( \rho \) is the degree of publicness. If \( \rho \) is zero, then government expenditure, \( G_t \), is purely public. On the other hand, if \( \rho \) is unity, then \( G_t \) is purely private. It needs to be noted that, when the value of \( \rho \) is large, the degree of publicness is low.

The flow budget constraint equation for each household at age \( s \) is

\[
A_{s+1}^i = \{1 + r(1 - \tau_r)\} A_s^i + \{1 - \tau_w(wx^i e_s) - \tau_p\} wx^i e_s + b_s^i + a_s^i - (1 + \tau_c) C_s^i, \tag{3}
\]

where \( A_s^i \) represents the amount of assets held by the household at the beginning of age \( s \), \( r \) the interest rate, \( w \) the wage rate per efficiency unit of labor, and \( e_s \) is the age profile of earnings ability for the household that belongs to the medium-income class. \( b_s^i \) is the amount of public pension benefit, and \( a_s^i \) is the amount of bequest to be inherited at age \( s \). \( \tau_w(wx^i e_s) \) is the tax rate on labor income, \( \tau_c \) that on consumption, \( \tau_r \) that on interest income, and \( \tau_p \) is the contribution rate to the public pension scheme. \( x^i \) is the weight coefficient corresponding to the different levels of labor endowments among the three income classes. The medium-income class is used as a yardstick, and thus \( x^m = 1 \). \( x^l \) and \( x^h \) reflect the realistic differences in earnings ability across the three income classes.

The tax system consists of labor income, interest income, consumption, and inheritance taxes. Labor income is progressively taxed. The symbol \( \tau_w(wx^i e_s) \) in equation (3) signifies that \( \tau_w \) is a function of \( wx^i e_s \). The progressive tax schedule is incorporated in the same manner as in Auerbach and Kotlikoff (1987): by choosing two parameters labeled \( \alpha \) and \( \beta \), we set the average tax rate \( \tau_w(wx^i e_s) \) equal

\[
Q = a_0 + a_1 A + a_2 A^2 + a_3 L + a_4 L^2,
\]

where \( Q \) denotes average monthly cash earnings, \( A \) age, and \( L \) the length of one’s service for all workers. Table 8 presents the parameter values estimated using data in the Ministry of Health, Labor and Welfare (2004). Because bonuses account for a large part of earnings in Japan, monthly cash earnings used here contain bonuses.

</tbody>
</table>

\( S.E. = 0.0847, R^2 = 0.9903. \)
to $\alpha + 0.5\beta w^xe_s$ for all values of $w^xe_s$. The corresponding marginal tax rate is $\alpha + \beta w^xe_s$. Setting $\beta = 0$ amounts to proportional taxation. One may make the tax system more progressive, holding revenue constant, by increasing $\beta$ and decreasing $\alpha$ simultaneously. On the other hand, interest income, consumption, and inheritances are proportionally taxed.

Variables related to the public pension program in a pay-as-you-go system are represented by

$$\begin{cases} b_i^j = \theta H_i^j & (s \geq ST) \\ b_i^j = 0 & (s < ST) \end{cases},$$

(4)

where the age at which each household starts to receive public pension benefits is $ST$, the average annual remuneration is $H_i^j = \frac{1}{RE-20} \sum_{s=21}^{RE} w^xe_s$, and the replacement ratio is $\theta$. Thus $b_i^j$ rigorously reflects different earnings abilities across the three income classes.

There are unintended bequests caused by uncertainty over the length of life. The bequests, which were held as assets by deceased households, are handed to surviving 50-year-old households. Therefore $d_i^j$ is positive if and only if $s = 50$, and otherwise is zero. The inheritance is transferred within the households that belong to the same income class. When $BQ_t^i$ is the sum of bequests inherited by 50-year-old households at period $t$, $d_i^{50}$ is defined by

$$d_i^{50} = \frac{(1 - \tau_h)BQ_t^i}{N_t p_5(1 + n)^{-29}},$$

(5)

where

$$BQ_t^i = N_t \sum_{s=21}^{95} (p_s - p_{s+1})(1 + n)^{-(s-21)} A_i^{s+1},$$

(6)

$N_t$ is the number of new households entering the economy as decision-making units at period $t$, $n$ is the common growth rate of successive cohorts, and $\tau_h$ is the tax rate on inheritances of bequests. In the steady state of a life-cycle growth model, the amount of inheritances received is linked to the age profile of assets chosen by individuals.

Let us consider the case in which each household maximizes lifetime utility under a constraint. Each household maximizes equation (2) subject to equation (3) (see Appendix A). From the utility maximization problem, the equation expressing evolution of consumption over time for each household is characterized by

$$C_i^{s+1} = \left[ \left( \frac{p_{s+1}}{p_s} \right) \left( \frac{1 + r (1 - \tau_r)}{1 + \delta} \right) \right]^\gamma C_i^s.$$

(7)

If the initial consumption level, $C_i^{21}$, is specified, optimal consumption behavior of all ages can be derived from equation (7). The amount of assets held by each household at each age can be obtained from equation (3). The expected lifetime utility of each household is derived from equation (2).
The social welfare function, which takes account of different earnings abilities and thus provides different levels of consumption, is given by

\[ SW = U^l + U^m + U^h. \]  

(8)

This function is derived from a summation of the expected lifetime utilities at age 21 for the three income classes. When comparing steady states, it is not necessary to take account of the utilities of all overlapping generations existing at period \( t \). A comparison of the lifetime utility of a single cohort is sufficient, because our aim is to compare the welfare level among simulation cases. The social welfare function is of the “Benthamite type”, but depends mainly on the utility of the low-income class, like the “Rawlsian type”\(^4\). It is maximized if all income classes have the same level of consumption.

With regard to the basic structure of firms, a single production sector is assumed to behave competitively using capital and labor, subject to a constant-returns-to-scale production function. See Appendix B for the basic structures of firms and the government, and market equilibrium conditions.

3. Simulation Analysis

The method of simulation employed in our analysis represents the economy as a general equilibrium system. We investigate an optimal tax rate on consumption, by comparing the equilibrium solutions that are calculated under given and counterfactual conditions. This method permits us to numerically calculate various economic variables and to recognize concrete policy implications. It is especially useful when examining policy packages, or when there are multiple policies that work in a differing direction.

3.1. Method of Simulation

The simulation model presented in the previous section is solved under the hypothesis of perfect foresight by households that correctly anticipate the interest, wage, tax, and contribution rates. If the tax and public pension systems are determined, the model can be solved using the Gauss-Seidel method (see Auerbach and Kotlikoff (1987) for the computation process). The parameter values \( \alpha \) and \( \beta \), which determine tax progressivity on labor income, and the tax rates on interest income (\( \tau_r \)) and inheritances (\( \tau_h \)), are exogenously given. Thus, tax revenue neutrality makes the tax rate on consumption (\( \tau_c \)) endogenous. With regard to the public pension system, the replacement ratio (\( \theta \)) is exogenously given. Therefore, the contribution rate (\( \tau_p \)) is made endogenous.

\(^4\) The model employs a simple utilitarian social welfare function based on the steady state utility for a single generation. The function is most sensitive to income changes for the low-income class due to the concavity of the underlying utility function. As the parameter of intertemporal elasticity of substitution, \( \gamma \), is lower, it depends more on the welfare of the low-income class. It becomes Rawlsian if \( SW = U^l \).

3.2. Simulation Cases

We consider three demographic regimes, namely, the 2005 current steady state and the 2025 and 2050 aged steady states. Case A is the current benchmark of 2005. Cases B and C are the benchmarks of an aged Japan projected for 2025 and 2050, respectively. Cases A, B, and C differ in population structure. Different survival probabilities ($p_s$) and different growth rates of successive cohorts ($n$) create different age structures of the population among the three demographic regimes (see Table 1 for the parameter values characterizing the three steady states).

Under conditions of aged steady states, Japan will face a decline in the proportion of its working population, with a subsequent decrease in aggregate output ($Y_t$); hence, the ratio of the total tax revenue ($T_t$) to aggregate output ($Y_t$) is raised, representing a substantial increase in the tax burden on an aging society. Under tax revenue neutrality, there is an extra burden caused by the transition from the current state (Case A) to the aged states (Cases B and C). In an aging society, tax policies that stimulate capital accumulation can be required; and for this a consumption tax promotes capital formation more than other tax regimes (see Okamoto (2004) for the details). Furthermore, there is the political possibility that the tax rate on consumption can be raised in present-day Japan. Therefore, in our simulation, a consumption tax covers the extra tax burden caused by transition to an aging society. Additionally, when maximizing social welfare, we consider cases in which the tax rate on consumption is adjusted.

The simulation results depend on the weight parameter, $\mu$, placed on public services in the utility function. The parameter value is assigned to 0.1 in the benchmark cases. Because the setting of the weight parameter is crucial for the aim of our analysis, a sensitivity analysis is undertaken. We consider simulation cases in which it is decreased to 0.01 and increased to 0.3. Also, the results depend on the parameter, $\rho$, which determines the degree of publicness on government expendi-

---

5) Population is the same across Cases A, B, and C. The population $AN_t$ is assigned to 180.98 in all simulation cases.

$^a$ The symbol ($^a$) before the rate indicates that the variable is exogenous.

$^b$ The parameter values that determine the tax progressivity on labor income are $\alpha = -0.0325$, $\beta = 0.0628$ in all simulation cases. The rate presented is an average tax rate on labor income.

3.2.1. Three benchmarks for 2005, 2025, and 2050

Table 2 shows the simulation results for the three benchmarks for 2005, 2025, and 2050.

**Case A** (Benchmark of the 2005 current state)

The utility weight, $\mu$, is set to 0.1. The tax system on labor income has a realistic progressiveness, with an average tax rate of 6.77%. Tax rates on consumption, interest income, and inheritances are 5%, 20%, and 10%, respectively.

**Cases B** (Benchmark of the 2025 aged state) and **C** (Benchmark of the 2050 aged state)

The utility weight, $\mu$, is the same as in Case A. The extra tax burden, caused by a transition to an aged society, is covered by a consumption tax. Other tax regimes remain the same as in Case A.

3.2.2. Cases that maximize social welfare for 2005, 2025, and 2050

Table 3 presents the simulation results in cases that maximize social welfare for the three benchmarks.
Table 3 Cases that maximize social welfare for 2005, 2025, and 2050

\(^a\) The symbol \((^*)\) before the rate indicates that the variable is exogenous.
\(^b\) The parameter values that determine the tax progressivity on labor income are \( \alpha = -0.0325 \), \( \beta = 0.0628 \) in all simulation cases. The rate presented is an average tax rate on labor income.

Case A*

In Case A, the tax rate on consumption is adjusted to maximize social welfare. A rise in the tax rate leads to an increase in government expenditure.

Cases B* and C*

In Cases B and C, the tax rate on consumption is adjusted to maximize social welfare, which gives Cases B* and C*, respectively.

3.2.3. Changes in the utility weight parameter given for public services for 2005, 2025, and 2050

In contrast to Cases A, B, and C, the weight parameter, \( \mu \), given for the benefits coming from government expenditure is changed to 0.01 and 0.3. Table 4 presents the simulation results of the transitions of an optimal tax rate on consumption, an optimal rate of the tax burden, and an optimal rate of the national burden for \( \mu = 0.01, 0.1, \) and \( 0.3 \).

Cases A-1 and A-2

In contrast to Case A, the utility weight, \( \mu \), is changed to 0.01 and 0.3, which yields Cases A-1 and A-2, respectively.

Cases A-1* and A-2*

In Cases A-1 and A-2, the tax rate on consumption is adjusted to maximize social welfare, which gives Cases A-1* and A-2*, respectively.

Cases B-1, B-2, B-1*, and B-2*
In the 2025 aged steady state, simulations similar to Cases-A are conducted. Cases B-1, B-2, B-1*, and B-2* correspond to Cases A-1, A-2, A-1*, and A-2*, respectively.

Cases C-1, C-2, C-1*, and C-2*
In the 2050 aged steady state, simulations similar to Cases-A are undertaken. Cases C-1, C-2, C-1*, and C-2* correspond to Cases A-1, A-2, A-1*, and A-2*, respectively.

3.2.4. Changes in the degree of publicness on government expenditure
Table 5 shows the simulation results for different degrees of publicness on government expenditure in the 2005 current benchmark case.

Case A-a
In contrast to Case A, the exponent, $\rho$, that determines the degree of publicness is decreased to 0.75, which yields Case A-a. In this case, government expenditure takes on more of the character of public goods.

Case A-b

In contrast to Case A, the exponent, $\rho$, is increased to unity, which gives Case A-b. In this case, government expenditure takes on the character of purely private goods.

Cases A-a* and A-b*

In Cases A-a and A-b, the tax rate on consumption is adjusted to maximize social welfare, which gives Cases A-a* and A-b*, respectively.

3.3. Specification of Parameters

This paper examines an optimal rate of the national burden for the economy in an aging Japanese society through comparing steady states. We choose parameter values that are realistic for the economy. Thus, the economic variables in the benchmark simulation (i.e., Case A), such as the ratio of capital to income ($K/Y$) or that of capital to labor ($K/L$), are close to the values that are suggested by the Economic and Social Research Institute (2005). The parameter values used in the simulation are given in Table 6.

First, the weight parameter, $\mu$, in the utility function in equation (2) is assigned to 0.1 in the benchmark cases. Because no studies have estimated explicitly this

Data given are for a couple with two children.

utility weight parameter, we made reference to Aschauer (1985) as a second-best means. In that study, effective consumption \(C^*\) is characterized by

\[ C^* = C + \phi G, \]

where \(C\) is private consumption and \(\phi\) denotes the degree of substitution between \(C\) and \(G\) (i.e., government spending). The parameter \(\phi\) signifies the marginal benefits of government expenditure. Aschauer’s study estimated \(\phi\) to lie between 0.2 and 0.4.

Second, survival probabilities (\(p_s\)) are calculated from the National Institute of Population and Social Security Research (2002). Our model makes no distinction by sex, and thus this study uses male–female average values for 2005, 2025, and 2050. Based on the above data, the percentages of the aged population (65 or over) in the total population (21 or over) in 2005, 2025, and 2050 are 24.90%, 34.63%, and 44.47%, respectively. Common growth rates of successive cohorts (\(n\)) are chosen so that the percentages in the simulation equal the estimated values (see Table 1).

Third, the method of assigning the weight given to labor endowments for the three income classes is explained. Table 7 shows the data from the Ministry of Finance (2005). This table presents the effective tax rates of wageworkers on a national income tax and a residence tax, with regard to a couple with two children. In our model, the three representative households, namely, low, medium, and high-income classes, have different earnings abilities. Table 7 suggests that each income class, which accounts for one third of the total population, corresponds to the representative household earning 5, 7, or 10 million yen, respectively, on an annual base. The weight on labor endowments for each income class corresponds to the ratio of its amount of earned income. The medium-income class is used as a yardstick, that is, \(x^m = 1\); \(x^l\) and \(x^h\) are assigned to reflect different earnings abilities across the three income classes.

Fourth, the method of assigning the parameter values that determine tax progressivity on labor income, namely, \(\alpha\) and \(\beta\), is described. Table 7 presents the effective tax rate calculated from a national income tax and a residence tax for each income class. The parameters on labor income are chosen so that the effective tax
rate for each income class in the simulation is close to the estimated value.

Finally, with regard to the public pension system, the replacement ratio of pension payments ($θ$) in Case A is adjusted so that the contribution rate ($τ_p$) equals the actual value of 13.58% in employee pension plans ($Kosei Nenkin$) in 2005.

4. Simulation Results

According to the Ministry of Finance (2005), the rate of the tax burden (= (National taxes + Local taxes) / National income) is 21.5%, the rate of social security (= Social security / National income) is 14.4%, and thus the rate of the national burden, which is the sum of them, was 35.9% in 2005. In our benchmark simulation (i.e., Case A), the rate of the tax burden is 12.94%, the rate of social security is 12.06%, and the rate of the national burden is 25.00%, as shown in Table 2. The rate of the tax burden in our simulation is substantially lower than the actual rate, because our model does not introduce such taxes as corporate and property ones. On the other hand, the rate of social security is close to the actual rate, although our simulation deals only with a public pension scheme. Therefore, in the setting of our simulation, the rate of the national burden is lower than that in reality in Japan.

This paper investigates an optimal tax rate on consumption to maximize the social welfare function. A rise in the tax rate on consumption increases the total tax revenue, which means an increase in government expenditure. This increase enhances households’ utility, because our model takes account of the benefits that the government provides to households. With regard to the social security system, our model only considers the current Japanese public pension program operated in a manner that is similar to a pay-as-you-go style. The replacement ratio in the current public pension system is kept constant in all simulations\(^6\). Therefore, it should be noted that an optimal rate of the national burden in this paper signifies the sum of an optimal rate of the tax burden (which is led by examining an optimal rate on consumption) and a constant rate of the public pension (= Public pension / National income).

In this paper, the influence on capital accumulation is regarded as an indicator of efficiency. The reason is that, under the assumption of an inelastic labor supply, the level of the total output depends solely on the level of the capital stock, as indicated by equation (14). The social welfare function represented by equation (8) is dependent on the aspects of both efficiency and equity.

\(^6\) Under a constant replacement ratio of the current Japanese public pension system, we maximize the social welfare. This is because, due to the rapid aging of the Japanese population, the benefits to be paid through the system are not profitable especially for future generations. Therefore, we decided that the current replacement ratio is also maintained in aged simulation cases.
4.1. Findings and Policy Implications

4.1.1. Three benchmarks for 2005, 2025, and 2050

Table 2 shows the simulation results for the three benchmarks for 2005, 2025, and 2050. Cases A, B, and C are the benchmarks for 2005, 2025, and 2050, respectively. Under revenue neutrality, a consumption tax covers an extra tax burden caused by the transition from the current state to the aged states. Therefore, in Cases B and C, the revenue-neutral tax rate on consumption is increased to 6.54% and 9.57%, respectively. As the population ages, the contribution rate to the public pension scheme (i.e., payroll tax) sharply rises under conditions of a constant replacement ratio. Table 1 suggests that the rate rises from 13.58% (Case A) to 21.57% (Case B) and 32.61% (Case C).

The capital-labor ($K/L$) ratio increases from 2.78 (Case A) to 3.10 (Case B), and then decreases slightly to 2.93 (Case C). The $K/L$ ratio is determined by the amounts of capital accumulation and labor supply. Both would decline as the population ages. With regard to capital formation, in an aging society, there are many cohorts that dissave their assets based on their life-cycle motive. With respect to the labor supply, it decreases drastically from 349.6 to 306.2 and 260.0 under a constant population, as shown in Table 1.

The rate of the tax burden rises from 12.94% (Case A) to 14.61% (Case B) and 17.31% (Case C), because there is the extra tax burden caused by transition to the aged states. The rate of social security dramatically rises from 12.06% (Case A) to 19.30% (Case B) and 29.06% (Case C), because the current public pension program is fundamentally a pay-as-you-go style. Thus, the rate of the national burden rises substantially from 25.00% (Case A) to 33.90% (Case B) and 46.37% (Case C).

4.1.2. Cases that maximize social welfare for 2005, 2025, and 2050

Table 3 presents the simulation results in cases that maximize social welfare for the three benchmarks for 2005, 2025, and 2050. In the current benchmark, the optimal tax rate on consumption rises drastically from 5% (Case A) to 20.17% (Case A*). As the population ages, it rises slightly to 20.38% (Case B*) and 20.45% (Case C*). The rate of the tax burden rises from 12.94% (Case A) to 23.71% (Case A*). As the population ages, it also rises slightly to 24.57% (Case B*) and 25.14% (Case C*). Thus, the rate of the national burden rises from 25.00% (Case A) to 35.77% (Case A*). As the population ages, it rises dramatically to 43.86% (Case B*) and 54.20% (Case C*), because of a substantial increase in the rate of social security.

Thus, the simulation results suggest that an optimal rate of the national burden would rise as the population ages and may exceed 50% during the rapid aging of the Japanese population. When evaluating this simulation result, the fact that the

7) The model in this paper does not introduce such taxes as corporate and property ones, while it takes full account of government expenditure. Therefore, in our simulation, the optimal tax rate on consumption inevitably becomes high. It should be noted that we do not claim that, in the current Japanese system, the optimal tax rate on consumption is approximately 20%.
rate of the national burden in the setting of our simulation is lower than the actual rate needs to be noted.

4.1.3. Changes in the utility weight parameter given for public services

With regard to the weight parameter, $\mu$, given for the benefits coming from government expenditure in equation (2), we assign 0.1 in the benchmark simulation. To ascertain the effects of different weight parameters on the simulation results, we consider the cases in which $\mu$ is changed to 0.01 and 0.3.

Table 4 shows that, when the weight is lowered to 0.01, the optimal tax rate on consumption decreases dramatically from 20.17% (Case A*) to 7.48% (Case A-1*). As the population ages, it rises slightly to 7.60% (Case B-1*) and 7.71% (Case C-1*). When the weight is raised to 0.3, the optimal tax rate on consumption increases to 29.34% (Case A-2*). As the population ages, it rises slightly to 29.61% (Case B-2*) and 29.65% (Case C-2*).

Table 4 also presents the simulation results for optimal rates of the tax burden and the national burden for 2005, 2025, and 2050. The results are similar to those for an optimal tax rate on consumption. When the utility weight parameter is high (i.e., $\mu = 0.3$) in 2050, the optimal rate of the national burden is approximately 60% (Case C-2*). The results suggest that, if households think highly of the benefits coming from government expenditure for their utility, the optimal tax rate on consumption (and thus the optimal rate of the national burden) is high.

To establish the relationship between the assignment of the utility weight parameter $\mu$ and the reality of the Japanese economy, an additional simulation was conducted. The result shows that the current Japanese tax rate on consumption of 5% is optimal when the weight parameter $\mu$ equals 0.0052. This means that, only when the utility weight for public services is this low, is the current tax rate on consumption justified.

4.1.4. Changes in the degree of publicness on government expenditure

With regard to the exponent, $\rho$, that determines the degree of publicness on government expenditure in equation (2), we assign 0.88 in the benchmark simulation, with reference to Borcherding (1985). To ascertain the effects of different degrees of publicness on the simulation results, we consider cases in which $\rho$ is changed to 0.75 and unity. In Case A-a where $\rho$ is 0.75, government expenditure takes on more of the character of public goods. On the other hand, in Case A-b where $\rho$ is unity, government expenditure is purely private goods.

Table 5 shows the simulation results for different degrees of publicness on government expenditure. When government expenditure takes on more of the character of public goods ($\rho = 0.75$), the optimal tax rate on consumption decreases dramatically from 20.17% (Case A*) to 8.64% (Case A-a*). Hence, in Case A-a*, the optimal rates of the tax burden and the national burden diminish to 15.80% and 27.86%, respectively. On the other hand, when government expenditure takes entirely on the character of purely private goods ($\rho = 1$), the optimal tax rate on consumption increases substantially to 37.47% (Case A-b*). Thus, in Case A-b*,
the optimal rates of the tax burden and the national burden increase to 33.09% and 45.15%, respectively.

Therefore, the simulation results suggest that, when the degree of publicness of government spending is high, that is, as government expenditure takes on more of the character of public goods, the optimal rate of the national burden is low. These results are generated by the concavity of the underlying utility function employed in our model.

4.2. Comments

For interpreting the simulation results, the following four comments need to be taken into account. First, our model assumes an inelastic labor supply. Therefore, there is only a partial impact of progressive taxation and no excess burden. An elastic labor supply needs to be introduced to comprehensively analyze the effects of tax reforms. Several investigations, however, showed that labor supply is fairly inelastic for the after-tax wage rate in Japan. For instance, Asano and Fukushima (1994) reported that the estimated value of compensated elasticity of labor supply is 0.27 in Japan. It should be noted that their study estimated only the size of the substitution effect. If the income effect were also estimated, a still smaller elasticity of labor supply for the after-tax wage rate would be obtained.

An elastic labor supply can be assumed by incorporating leisure into the utility function in addition to consumption, such as in Auerbach and Kotlikoff (1987), Altig et al. (2001), and Okamoto (2007):

\[
U^i = \frac{1}{1 - \frac{1}{\gamma}} \sum_{s=21}^{95} p_s (1 + \delta)^{-(s-21)} \left\{ (C_s^i)^{1-\gamma} + \phi (l_s^i)^{1-\gamma} \right\}^{\frac{1}{1-\gamma}},
\]

where \(l_s^i\) represents leisure at age \(s\), \(\phi\) the utility weight on leisure, and \(\xi\) is the intratemporal elasticity of substitution between consumption and leisure. The weight on leisure \(\phi\) is assigned to 1.5 in Auerbach and Kotlikoff (1987) and 1.0 in Altig et al. (2001), respectively. On the other hand, Homma et al. (1987b) estimate the weight parameter to be 0.1 using Japanese data, which is much smaller than that in the United States. Thus, the parameter \(\phi\) is assigned to 0.1 in studies on the Japanese economy, such as in Homma et al. (1987a), Iwamoto (1990), and Uemura (2001). Such a large difference may suggest that, even if elastic labor supply were introduced, the simulation results would not change so much as long as we conduct the analysis on the Japanese economy.

Second, our simulations are limited to the steady states. The model takes account of the effects of demographics, by comparing the three steady states for 2005, 2025, and 2050. Thus, our study lacks a consideration of the transitional path. Tax and social security reforms have different effects on different generations. Specifically, current and future generations would experience different impacts of these
reforms\textsuperscript{8}). Therefore, it is necessary to take account of not only steady states but also the transitional process in an aging society.

Third, the simulation model is solved under the hypothesis of perfect foresight. Households correctly anticipate the interest, wage, tax, and contribution rates. Without the assumption of perfect foresight, households that maximize their lifetime utility would have more assets, resulting in more capital accumulation. As households are more risk averse, this effect is greater.

Finally, because the simulation results are dependent on the given parameters, we must be careful about the effects of any parameter changes. As shown in Tables 4 and 5, a slight change in the parameters of $\mu$ (the weight on public services) and $\rho$ (the degree of publicness) in the utility function has a substantial effect on the results. Also, a slight change in the parameter of intertemporal elasticity of substitution, $\gamma$, has a great affect on capital formation.

5. Conclusions

This paper examined an optimal rate of the national burden to establish guidelines for fiscal reform in Japan’s graying society. The paper looked at Japanese tax and social security systems through an extended life-cycle general equilibrium simulation model. It considers the benefits that the government provides to households, which enabled us to comprehensively evaluate the balance between benefits and burdens.

The simulation results showed that, when households put a great utility weight on the benefits coming from public services, an optimal rate of the national burden is high. This implies that, if the government appropriately provides public services that meet the demands of households, the optimal rate is high. The results also suggested that, when the degree of publicness of government expenditure is high, an optimal rate of the national burden is low. In other words, if government expenditure takes on more of the character of public goods, the optimal rate is low.

Moreover, the simulation results indicated that, as the population ages, an optimal tax rate on consumption rises gradually and the contribution rate to the public pension program with a pay-as-you-go scheme dramatically rises under conditions of a constant replacement ratio. Therefore, an optimal rate of the national burden would rise as the population ages, and may exceed 50% during the rapid aging of the Japanese population.

\textsuperscript{8}) For example, a change from a labor income tax to a consumption tax creates income transfers among generations during the transition. At the onset of policy reform, the elderly who had already paid their labor income tax will have to pay an additional consumption tax. Because this generation would suffer from a double burden, the transition to a consumption tax is not Pareto improving.
Appendix A

To consider the utility maximization problem over time for each income class, namely the maximization of equation (2) subject to equation (3), let the Lagrange function be

\[ L^i = U^i + \sum_{s=21}^{95} \lambda^i_s \left[ -A^i_{s+1} + \{1 + r(1 - \tau_r)\} A^i_s + \{1 - \tau_w(wx^i e_s) - \tau_p p_x e_s + b^i_s + a^i_s - (1 + \tau_c) C^i_s \} \right], \tag{9} \]

where \( \lambda^i_s \) represents the Lagrange multiplier for equation (3) and superscripts \( i (=l, m, h) \) denote low, medium, and high-income classes, respectively. The first-order conditions for \( s = 21, 22, \ldots, 95 \) can be expressed by

\[ \frac{\partial L^i}{\partial C^i_s} = p_s (1 + \delta)^{-(s-21)} \{ C^i_s \}^{-\frac{1}{\gamma}} - \lambda^i_s (1 + \tau_c) = 0, \tag{10} \]

\[ \frac{\partial L^i}{\partial A^i_{s+1}} = -\lambda^i_s + \lambda^i_{s+1} \{1 + r(1 - \tau_r)\} = 0. \tag{11} \]

The combination of equations (10) and (11) yields equation (7) that determines the slope of the age-consumption profile over the life cycle. For a given \( C^i_{21} \), equation (7) solves the path for consumption. Transformation of equation (7) leads to the following expression:

\[ C^i_s = \left( \frac{p_s}{p_{21}} \right)^{\gamma} \left\{ \frac{1 + r(1 - \tau_r)}{1 + \delta} \right\}^{\gamma(s-21)} C^i_{21}. \tag{12} \]

Integrating equation (3) and using the initial and terminal conditions \( A^i_{21} = A^i_{96} = 0 \), caused by no intended bequests, produces the following equation:

\[ \sum_{s=21}^{95} \{1 + r(1 - \tau_r)\}^{-(s-21)} (1 + \tau_c) C^i_s \]

\[ = \sum_{s=21}^{RE} \{1 + r(1 - \tau_r)\}^{-(s-21)} [1 - \tau_w(wx^i e_s) - \tau_p p_x e_s] w e_s \]

\[ + \sum_{s=ST}^{95} \{1 + r(1 - \tau_r)\}^{-(s-21)} b^i_s + \{1 + r(1 - \tau_r)\}^{-29} a^i_{50}. \tag{13} \]

To derive \( C^i_{21} \), equation (12) is substituted into this lifetime budget constraint. Thus, we can find an optimum solution for \( C^i_{21} \).
Appendix B

Section 2 describes the basic structure of households in the simulation model. This appendix presents the basic structures of firms and the government, and market equilibrium conditions.

Firm Behavior

The model has a single production sector that is assumed to behave competitively using capital and labor, subject to a constant-returns-to-scale production function. Capital is homogeneous and non-depreciating, while labor differs only in its efficiency. All forms of labor are perfect substitutes. Households in different income classes or of different ages, however, supply different amounts of some standard measure per unit of labor input.

The production function is assumed to be of the constant elasticity of substitution form:

\[ Y_t = B \left[ \epsilon K_t^{1-\frac{1}{\sigma}} + (1-\epsilon)L_t^{1-\frac{1}{\sigma}} \right]^{\frac{1}{1-\sigma}}, \]  

(14)

where \( Y_t \) represents the total output, \( K_t \) the total capital, \( L_t \) the total labor supply measured by the efficiency units, \( B \) a scaling constant, \( \epsilon \) a parameter measuring the intensity of use of capital in production, and \( \sigma \) is the elasticity of substitution between \( K_t \) and \( L_t \). Using the property subject to a constant-returns-to-scale production function, we can obtain the following equation:

\[ Y_t = rK_t + wL_t. \]  

(15)

Government Behavior

The government sector consists of a narrower government sector and a pension sector. The narrower government sector collects taxes and spends them on general governmental expenditure. There is no outstanding debt, and thus balanced budget policies are assumed.

The budget constraint of the narrower government sector at time \( t \) is given by

\[ G_t = T_t, \]  

(16)

where \( T_t \) is the total tax revenue from labor income, interest income, consumption, and inheritances. The public pension system is assumed to be a simple pay-as-you-go scheme. The budget constraint of the pension sector at time \( t \) is given by

\[ R_t = B_t, \]  

(17)

where \( R_t \) is the total contribution to the pension schedule, and \( B_t \) is the total pension benefit to generations of age \( ST \) or over.

Both of these sectors are financed independently and separately. No transfer is
made between the sectors. $G_t, T_t, R_t$ and $B_t$ are defined by

\[ G_t = N_t \sum_{s=21}^{95} p_s (1 + n)^{-(s-21)} g, \]  
\[ T_t = L X_t + \tau_r r A S_t + \tau_r A C_t + \tau_h B Q_t, \]  
\[ R_t = \tau_p w L_t, \]  
\[ B_t = N_t \sum_{s=ST}^{95} p_s (1 + n)^{-(s-21)} [ b^l_s + b^m_s + b^h_s ], \]

where $g$ is annual government expenditure for each cohort, and

\[ B Q_t = B Q^l_t + B Q^m_t + B Q^h_t. \]

$L X_t$ is the tax revenue from labor income, which is led by a summation of the three income classes with the same weight:

\[ L X_t = N_t \sum_{s=21}^{RE} p_s (1 + n)^{-(s-21)} \left[ \alpha w x^l e_s + \frac{1}{2} \beta (w x^l e_s)^2 + \alpha w x^m e_s \right. \]
\[ + \frac{1}{2} \beta (w x^m e_s)^2 + \alpha w x^h e_s + \frac{1}{2} \beta (w x^h e_s)^2 \].

Similarly, aggregate assets supplied by households, $A S_t$, and aggregate consumption, $A C_t$, are obtained by a simple summation of the three income groups:

\[ A S_t = N_t \sum_{s=21}^{95} p_s (1 + n)^{-(s-21)} [ A^l_s + A^m_s + A^h_s ], \]
\[ A C_t = N_t \sum_{s=21}^{95} p_s (1 + n)^{-(s-21)} [ C^l_s + C^m_s + C^h_s ]. \]

**Market Equilibrium**

Finally, equilibrium conditions for the capital, labor, and goods markets are described.

1. **Equilibrium condition for the capital market**
   
   Because aggregate assets supplied by households are equal to real capital, we get
   
   \[ A S_t = K_t. \]
2. Equilibrium condition for the labor market

Measured in efficiency units, because aggregate labor demand by firms is equal to aggregate labor supply by households, we get

\[
L_t = N_t \sum_{s=21}^{RE} p_s (1 + n)^{-(s-21)} \{x^j + x^m + x^h\} e_s. \tag{27}
\]

3. Equilibrium condition for the goods market

Because aggregate production is equal to the sum of consumption, investment, and government expenditures, we get

\[
Y_t = AC_t + (K_{t+1} - K_t) + G_t. \tag{28}
\]

An iterative program is performed to obtain the equilibrium values of the above equations.

This paper was presented at the 61st Congress of the International Institute of Public Finance (IIPF) in Korea in 2005, and at the Spring Seminar of the Department of Economics at the University of Wisconsin-Milwaukee in 2006. The author is very grateful for insightful comments and suggestions by Professors Toshiaki Tachibanaki, Sunwoong Kim, Mohsen Bahmani-Oskooee, Yoshio Niho, Masaru Yoshitomi, Yuji Hosoya, Nobuhiko Yamazaki, Masayuki Morikawa, Toshiya Hatano, Masumi Kawade, Naomi Miyazato, and Syun-ichiro Bessyo. The author acknowledges the financial supports from the Research Institute of Economy, Trade and Industry (RIETI) in Japan, and from the Ministry of Education, Culture, Sports, Science and Technology in Japan (Grant-in-Aid for Scientific Research (C) No.15530215). This research is also a part of the International Research Project on Aging (Japan, China, and Korea) at Hosei Institute on Aging (Hosei University), supported by the Special Assistance of the Ministry of Education, Culture, Sports, Science and Technology in Japan.
