INTRODUCTION

Prostaglandin (PG) E₂ is a major metabolite of arachidonic acid liberated from phospholipids in plasma membranes. PGE₂ is synthesized from arachidonic acid through oxygenation and reduction by prostaglandin H synthase (cyclooxygenase) and isomerization by PGE synthase (Fig. 0-1). PGE₂ produces a broad range of biological actions in diverse tissues through binding to specific receptors on plasma membranes (Samuelsson et al., 1978; Moncada et al., 1985). Pharmacological studies have suggested that there are four subtypes of PGE receptors, EP₁, EP₂, EP₃ and EP₄, which are thought to differ in their signal transduction mechanisms; these receptors are coupled to Ca²⁺ mobilization (EP₁), or the stimulation (EP₂ and EP₄) or inhibition (EP₃) of adenylate cyclase (Coleman et al., 1990; Negishi et al., 1993; Coleman et al., 1994). Various pharmacological actions of PGE₂ via these receptor subtypes have been characterized (Table 1).

The receptor subtype EP₂, which is coupled to the stimulation of adenylate cyclase, is known to be involved in PGE₂-induced relaxation of the trachea and ileal smooth muscle (Gardiner, 1986; Botella et al., 1993). In addition, PGE₂ has been shown to increase the cAMP level in many tissues and cells (Samuelsson et al., 1978; Coleman et al., 1990), suggesting that EP₂ is widely distributed and mediates various actions of PGE₂. This idea however, is not conclusive because most pharmacological studies have been performed using PGE₂ as an agonist, but not with ligands selective to EP₂. PGE₂ has been reported to increase the cAMP level through its interaction with EP₂ and/or EP₄ (Honda et al., 1993; Coleman et al., 1994; Nishigaki et al., 1995). Therefore, it is necessary to clarify the functions of EP₂ at the molecular level, and to elucidate which subtype is involved in each cAMP-mediated action of PGE₂.
The author at first isolated a cDNA encoding the mouse EP2, and then using this cDNA, characterized its structural, binding and signaling properties and its tissue distribution (Katsuyama et al., 1995). The author also found that the mRNAs for the EP2 as well as other EP subtypes show distinct cellular localizations in pseudopregnant mouse uteri, and that the EP2 mRNA is specifically expressed on day 5 and its expression is confined to the luminal epithelium (Katsuyama et al., 1997). Furthermore, the author found tissue specific initiation of transcription of the EP2 gene in the macrophage and the uterus (Katsuyama et al., 1998).

The results obtained are described in the following, divided into three chapters.

1. The Mouse Prostaglandin E Receptor EP2 Subtype: Cloning, Expression, and Northern Blot Analysis

ABSTRACT

A functional cDNA clone for the mouse PGE receptor subtype EP2 was isolated from a mouse cDNA library. The mouse EP2 consists of 362 amino acid residues with seven putative transmembrane domains. [3H]PGE2 bound specifically to the membrane of Chinese hamster ovary (CHO) cells stably expressing the cloned receptor. This binding was displaced by unlabeled prostanoids, in the order of efficiency of PGE2 = PGE1 >> iloprost, a stable PGI2 agonist > PGF2α > PGD2. Binding was also inhibited by butaprost (an EP2 agonist) and to a lesser extent by M&B 28767 (an EP3 agonist), but not by sulprostone (an EP1 and EP3 agonist) or SC-19220 (an EP1 antagonist). PGE2 and butaprost increased the cAMP level in the CHO cells in a concentration-dependent manner. Northern blot analysis revealed that EP2 mRNA is expressed most abundantly in the uterus, followed by the spleen, lung, thymus, ileum, liver, and stomach.
RESULTS

Structure of the Mouse EP2 Receptor

A mouse cDNA clone, ML202, was isolated by PCR and subsequent screening of a mouse lung cDNA library. Figure 1-1 shows the nucleotide sequence and deduced amino acid sequence of ML202. ML202 contains a 1.7 kb insert which has an open reading frame of 1,086 bp. The deduced amino acid sequence showed that it encodes a protein of 362 amino acid residues with an estimated molecular weight of 40,478. The ATG assigned as the initiation codon matched well to the Kozak consensus sequence for translation initiation (Kozak, 1989). Analysis of the predicted amino acid sequence indicated that it possesses seven hydrophobic segments typical of guanine nucleotide-binding protein-coupled rhodopsin-type receptors, and is 86% identical to that of the human EP2 (Regan et al., 1994). A potential N-glycosylation site (Bause, 1983) was found in both the N-terminal and the first extracellular loop regions. Five potential sites of phosphorylation by protein kinase C (Woodgett et al., 1986) were found in the second and third intracellular loops and the C-terminal regions.
Fig. 1-1. Nucleotide sequence and deduced amino acid sequence of ML202. The deduced amino acid sequence is shown beneath the nucleotide sequence using the single-letter code. The positions of the putative transmembrane segments, I-VII, are underlined. Triangles, potential N-glycosylation sites. Parallel crosses, potential sites of phosphorylation by protein kinase C.
Membranes of CHO cells expressing the cloned receptor showed specific binding of $[^3\text{H}]$PGE$_2$. Scatchard analysis of this binding yielded a dissociation constant of 26.7 nM and maximal binding of 822 fmol/mg protein. Figure 1-2 shows the specificity of this binding. As shown in Fig. 1-2a, specific $[^3\text{H}]$PGE$_2$ binding was displaced by unlabeled prostanoids, in the order of efficiency of PGE$_2 = $PGE$_1 >>$ iloprost, a stable PGI$_2$ agonist $>$ PGF$_{2\alpha}$ $>$ PGD$_2$. This result indicates that ML202 encodes a specific PGE receptor. As shown in Fig. 1-2b, further analyses using several ligands selective to PGE receptor subtypes demonstrated that the binding was also inhibited by butaprost (an EP$_2$ agonist) and to a lesser extent by M&B 28767 (an EP$_3$ agonist), but not by sulprostone (an EP$_1$ and EP$_3$ agonist) or SC-19220 (an EP$_1$ antagonist). These results indicate that ML202 encodes the mouse EP$_2$. The binding specificity of the mouse EP$_2$ was further characterized using various additional ligands, including additional EP$_2$ agonists. As shown in Fig. 1-2c, specific $[^3\text{H}]$PGE$_2$ binding was also inhibited by several additional ligands, in the order of efficiency of 16,16-dimethyl PGE$_2$ (a nonselective EP agonist) (Nishigaki et al., 1995; Regan et al., 1994) $>$ 11-deoxy PGE$_1$ (an EP$_2$, EP$_3$, and EP$_4$ agonist) (Nishigaki et al., 1995; Regan et al., 1994) $>$ misoprostol (an EP$_2$, EP$_3$, and EP$_4$ agonist) (Honda et al., 1993; Coleman et al., 1988; Reeves et al., 1988) $>$ 1-OH-PGE$_1$ (an EP$_4$ partial agonist) (Nishigaki et al., 1995) $>$ 19(R)OH-PGE$_2$ (an EP$_2$ agonist) (Regan et al., 1994; Woodward et al., 1993). These binding characteristics were in good agreement with those of the human EP$_2$ (Regan et al., 1994), except for poor reactivity of 19(R)OH-PGE$_2$ to the mouse receptor. This may at least in part be due to species differences between the two receptors.

Signal Transduction Pathway of the Mouse EP₂ Receptor

Next, the signal transduction pathway of the mouse EP₂ was examined. As shown in Fig. 1-3, PGE₂ generated cAMP in a concentration-dependent manner in CHO cells expressing EP₂. In addition, butaprost and 11-deoxy PGE₁ were also effective in stimulating cAMP formation in the cells, although their half-maximal concentrations for this effect were about 10-fold higher than that of PGE₂. 19(R)OH-PGE₂ and 1-OH-PGE₁ were less effective than the ligands described above. It was also examined whether PGE₂ induces accumulation of inositol phosphates, but PGE₂ did not evoke phosphatidylinositol hydrolysis in the cells (data not shown), as is the case in EP₄ (Honda et al., 1993).

PGE₂ has been shown to increase the cAMP level in many tissues and cells (Samuelsson et al., 1978) through its interaction with EP₂ and/or EP₄. To elucidate which PGE receptor subtype is involved in cAMP-mediating actions of PGE₂ in each tissue, the expression patterns of EP₂ and EP₄ were compared by Northern hybridization. As shown in Fig. 1-4a, the level of EP₂ expression was much lower than that of EP₄ in most of the tissues examined. In a previous report, using standard hybridization analysis, Regan et al. detected EP₂ mRNA only in the mRNA from the human placenta and lung, and not in the other tissues (Regan et al., 1994). Therefore, highly purified poly(A)+ RNAs were utilized for more sensitive detection (Fig. 1-4b). As a result, a positive band at 2.2 kb was detected in a number of tissues in which EP₂ had been identified in pharmacological studies (Coleman et al., 1990); the tissues include the uterus, lung, ileum, liver, stomach, thymus and spleen. Another hybridizing band was also seen at 2.8 kb in the uterus. These data demonstrate that EP₂ is widely distributed throughout the mouse tissues.

DISCUSSION

*Structural Similarities between the Mouse EP2 Receptor and Other Prostanoid Receptors*

Figure 1-5 shows the comparison of the amino acid sequences among the cloned mouse prostanoid receptors (Sugimoto et al., 1992; Namba et al., 1992; Honda et al., 1993; Watabe et al., 1993; Sugimoto et al., 1994a; Namba et al., 1994; Hirata et al., 1994). EP2 showed a higher degree of homology to DP, IP, and EP4 than to the other prostanoid receptors (Table 2). It is understandable from the viewpoint of phylogeny that EP2, DP, IP, and EP4 are all coupled to stimulation of adenylate cyclase. Among these receptors, EP2 possesses higher sequence homology with DP and IP than with EP4; EP2 shares 44, 39, and 31% overall amino acid identity with DP, IP, and EP4, respectively. This indicates that the divergence between EP2 and EP4 occurred before the derivation of DP and IP from EP2 (Toh et al., 1995).

Fig. 1-5. Comparison of the amino acid sequences of mouse prostanoid receptors.

The deduced amino acid sequences of the mouse EP2 (mEP2), mouse PGD receptor (mDP), mouse PGI receptor (mIP), mouse EP4 (mEP4), mouse EP3α (mEP3α), mouse EP1 (mEP1), mouse PGF receptor (mFP), and mouse TXA2 receptor (mTP) are aligned to optimize homology. Identical amino acid residues in four or more sequences are indicated by bold characters. The approximate positions of the putative transmembrane regions are indicated above the amino acid sequences.
Physiological Function of the EP2 Receptor

Tissue distribution of the mRNA for the mouse EP2, together with those for other PGE receptor subtypes, are shown in Fig. 1-6. The highest level of EP2 mRNA expression is seen in the uterus, in which EP3 and EP4 are also expressed. Cellular distributions of these PGE receptor subtypes in the uterus were investigated and their physiological functions are discussed in Chapter 2. Both EP2 and EP4 are expressed in the ileum and thymus. PGE2 and butaprost have been reported to cause relaxation of the ileal smooth muscle (Botella et al., 1993), while PGE2 also stimulates intestinal secretion via the elevation of mucosal cAMP levels (Musch et al., 1987; Bunce et al., 1987; Homaidan et al., 1995). It is likely that EP2 and EP4 are involved in relaxation of the intestinal smooth muscle and stimulation of intestinal secretion, respectively. The EP2 transcript was detected in the liver, in which no signals for the EP4 transcript were detected. PGE2 has been reported to be involved in liver regeneration (Tsujii et al., 1993), and PGE2 and other cAMP-elevating agents can induce the expression of hepatocyte growth factor (Matsunaga et al., 1994). EP2 might be involved in these actions of PGE2. EP2 was also expressed in the spleen, lung, and stomach. Although other PGE receptor subtypes are also expressed in the lung (Sugimoto et al., 1992; Watabe et al., 1993), EP2 may be partly involved in the PGE2-induced relaxation of the trachea (Gardiner, 1986).
Fig. 1-6. Northern blot analysis of the mRNAs for four subtypes of the mouse PGE receptor.
2. Distinct Cellular Localization of the Messenger Ribonucleic Acid for Prostaglandin E Receptor Subtypes in the Mouse Uterus during Pseudopregnancy

ABSTRACT

As an initial step to clarify the mechanisms of various uterine actions of PGE2, expression patterns of the mRNAs for four subtypes of PGE receptors, EP1, EP2, EP3, and EP4, were investigated in the mouse uterus during pseudopregnancy. Relative expression levels were investigated by Northern blot analysis of mRNA levels in uteri obtained on days 0, 1, 3, 5, 7, and 9 of pseudopregnancy (day 0 = 48 h after PMSG injection), and cellular localization was determined by in situ hybridization in uteri obtained on days 0 and 5. EP2 mRNA was specifically expressed on day 5, and its expression was confined to the luminal epithelium. On the other hand, the level of the EP3 mRNA expression progressively increased until day 5. Cell populations expressing the EP3 mRNA were confined to the longitudinal smooth muscle on day 0, but they changed to the circular smooth muscle on day 5. The expression level of EP4 mRNA was low on days 0 and 1, but became high on days 3 and 5. On day 0, EP4 mRNA was localized to the luminal epithelium. On day 5, EP4 expression was observed over the endometrial stroma and epithelium. This expression was diffuse, but still significant. No EP1 mRNA signals were observed. Transient expression of EP2 on day 5 of pseudopregnancy in the luminal epithelium suggests its involvement in blastocyst implantation signaling. EP4 in the endometrial stroma is suggested to be involved in decidual transformation of stromal cells, whereas EP3 in the myometrium is believed to be involved in regulation of myometrial activity.
RESULTS

Changes in the expression levels of the PGE receptor mRNAs in the uterus during pseudopregnancy

In the uteri from pseudopregnant mice, the mRNAs encoding the three PGE receptor subtypes, EP2, EP3, and EP4, were detected by Northern blot analyses (Fig. 2-1a); the major transcripts were 2.8, 2.3, and 3.9 kb for EP2, EP3, and EP4, respectively. Minor bands for the EP2 and EP3 mRNAs were also observed, as reported previously (Sugimoto et al., 1992; Katsuyama et al., 1995). No expression of the EP1 transcript was detected (data not shown). The level of expression of the EP2 transcript showed marked variations during the period examined. The transcript was barely detectable on days 0 and 1 of pseudopregnancy. On day 3, EP2 mRNA was detected at a very low level, and the increase was evident on day 5: the mRNA level was 11-fold the level on day 3. The EP2 mRNA thereafter sharply decreased to that seen on day 3. EP3 mRNA was hardly detected on day 0. Beginning on day 1, the transcript progressively increased in abundance to reach the maximum on day 5, which was about 13-fold the level observed on day 1 (Fig. 2-1b). On days 7 and 9, expression decreased to lower levels than those on day 3. The expression of EP4 mRNA, which was low on days 0 and 1, progressively increased and was maintained at a high level after day 5, which was approximately 10- to 15-fold the level on day 0 (Fig. 2-1b).
Fig. 2-1. a, Time-dependent expression of the mRNAs for PGE receptor subtypes in the mouse uterus during pseudopregnancy. Uteri were collected from three mice for each day of pseudopregnancy studied, and total RNAs were isolated. mRNA values were determined by Northern blot analysis using \textsuperscript{32}P-labeled antisense riboprobes as described in "EXPERIMENTAL PROCEDURES." The same blots were rehybridized with \textsuperscript{32}P-labeled DNA probe for GAPDH, and the representative results are shown. The day of pseudopregnancy is shown at the top. Day 0 represents 48 h after PMSG injection. The positions of the major bands are indicated by arrowheads. b, Quantitation of the signals for the PGE receptor (EP) mRNAs in a. The autoradiograms were subjected to densitometric scanning, and EP mRNA levels were normalized to GAPDH mRNA levels. The increase in EP mRNA levels is expressed as the fold increase over the level on the control day (days 3, 1, and, 0 for EP\textsubscript{2}, EP\textsubscript{3}, and EP\textsubscript{4}, respectively). Northern blot analyses were independently repeated three times, and similar results were obtained. Representative results are shown.
Cellular localization of PGE receptor mRNAs in the pseudopregnant uterus

To define the cell populations expressing the PGE receptor subtype mRNAs, \textit{in situ} hybridization analysis was performed on uteri on days 0 and 5 of pseudopregnancy. \textit{In situ} hybridization using $^{35}$S-labeled riboprobes revealed distinct regional distributions of EP$_2$, EP$_3$, and EP$_4$ mRNAs in the uterus. No signals for the EP$_1$ mRNA were detected in uteri on days 0 and 5 (Fig. 2-4b for day 5).

On day 0 of pseudopregnancy, EP$_3$ and EP$_4$ mRNAs were detected in the uteri (Fig. 2-2, c and d), but no significant signals for EP$_2$ were seen (Fig. 2-2b). Hybridization signals for the EP$_3$ mRNA were found in the myometrium (Fig. 2-2c). Microscopic examination of the myometrium exhibited weak, but significant, labeling of the longitudinal smooth muscle cells, but the circular smooth muscle cells were hardly labeled with the EP$_3$ probe (Fig. 2-3, a and b). As shown in Fig. 2-3, c and d, signals for the EP$_4$ mRNA were localized in the luminal epithelium.

On day 5 of pseudopregnancy, strong hybridization signals for EP$_2$ mRNA were observed in the luminal epithelial cells (Figs. 2-4c and 2-5, a and b). As shown in Fig. 2-4d, strong hybridization signals for EP$_3$ mRNA were seen in the myometrium. Microscopic examination of the myometrium exhibited intense labeling of the circular smooth muscle cells, but the longitudinal smooth muscle cells were not labeled (Fig. 2-5, c and d). Diffuse, but significant, EP$_4$ expression was observed in the endometrium (Fig. 2-4e). Microscopic examination of the endometrium revealed significant labeling of the luminal epithelial cells like that on day 0 of pseudopregnancy. In addition, endometrial stromal cells and the glandular epithelium were also labeled (Fig. 2-5, e and f).

PGE₂ is a major metabolite of arachidonic acid synthesized by cyclooxygenase pathways in the uterus, and has been demonstrated to be produced at implantation sites and the amnion and decidua at the onset of labor (Parr and Parr, 1989; Soloff, 1989). PGE₂ regulates various uterine functions, such as contraction and relaxation of the uterine smooth muscles, cervical ripening and labor induction, elevation of endometrial vascular permeability, and induction of decidualization (Weitlauf, 1988; Parr and Parr, 1989; Soloff, 1989; Huszar and Walsh, 1989; Coleman et al., 1990). PGE₂-binding activity has been determined in the myometrium in various species (Coleman et al., 1990; Senior et al., 1991; Goureau et al., 1992; Senior et al., 1993), and changes in the number of binding sites, depending on the state of pseudopregnancy or the estrous cycle, have been reported regarding the endometrium (Kennedy et al., 1983a; Hofmann et al., 1985; Kennedy et al., 1986). However, the contributions of the four receptor subtypes to PGE₂-induced uterine actions have not yet been well established, except for the contractile action on the myometrium, which is probably mediated by EP₃ (Senior et al., 1991; Goureau et al., 1992; Senior et al., 1993). Using isolated cDNAs encoding four PGE receptor subtypes (Sugimoto et al., 1992; Honda et al., 1993; Watabe et al., 1993; Nishigaki et al., 1995; Katsuyama et al., 1995), their cellular distribution in pseudopregnant mouse uteri was investigated by Northern blot and in situ hybridization analyses.

The present study demonstrated time-dependent changes in expression levels and distinct cellular localizations of the mRNAs encoding the three subtypes of PGE receptors, EP₂, EP₃, and EP₄, in the mouse uterus during pseudopregnancy. Such time-dependent
fluctuation of PGE receptor mRNAs has not been identified in other tissues or systems other than the uterus. In this study, mice were administered PMSG; on day 0, defined as 48 h after injection, mice were regarded as being in the proestrous stage by analysis of vaginal smears or by confirmation of ovulation on the following morning. On the other hand, day 5 was regarded as the time of maximal uterine sensitivity to the presence of blastocysts (Moulton and Koenig, 1986; Markoff et al., 1995). In the present study, superovulation of immature mice and induction of pseudopregnancy were used as a model system to examine the changes in PGE receptor expression. Although this system is known to include nonphysiological hormonal stimuli, preliminary in situ hybridization was performed on pseudopregnant day 5 mice that were generated from mature and cycling females, and consequently almost the same results as achieved using superovulated day 5 mice were obtained (data not shown).

The mRNA encoding EP2, which is coupled to the stimulation of adenylate cyclase, was expressed almost exclusively on day 5 of pseudopregnancy, and its expression was confined to the luminal epithelium. This observation is inconsistent with the previous report that no \[^{3}H\]PGE\textsubscript{2}-binding sites were detected in the luminal epithelium (Kennedy et al., 1983b). In this previous study, however, binding experiments were performed using the uterine epithelium of progesterone-treated ovariectomized rats, not that of rats on day 5 of pseudopregnancy. The high level selective expression of EP2 on day 5 suggests the involvement of PGE\textsubscript{2} in blastocyst implantation, which occurs during days 4 and 5 of pregnancy in the mouse (Markoff et al., 1995; Das et al., 1992; Schiff et al., 1993). It has been noted that cyclooxygenase-2 (COX-2) is transiently expressed on day 4.5 of pregnancy in the luminal epithelium (Jacobs et al., 1994). Considering
the similarity in fluctuation between EP2 and COX-2 expression, PGE2 synthesized in the luminal epithelium may exert its effect through EP2 in an autocrine manner. EP2 might mediate signals for morphological changes in the luminal epithelium essential for blastocyst implantation (Parr and Parr, 1989). In fact, treatment with indomethacin, a COX-inhibitor, has been shown to elicit ultrastructural changes in the luminal epithelium and to inhibit blastocyst implantation (Lundkvist and Nilsson, 1980). Thus, EP2 expressed in the luminal epithelium might be involved in transmission of the signal from the blastocyst to the underlying stromal cells.

The expression of EP4, which is also positively coupled to adenylate cyclase, sharply increased on day 3 of pseudopregnancy. This increase may be reflecting the change in stromal cells; EP4 mRNA was expressed in the stroma on day 5, but not on day 0. As the serum progesterone level was reported to rise and reach its maximum on day 5 of pseudopregnancy in the rat (Pepe and Rothchild, 1974), it is possible that EP4 expression in stromal cells is induced by progesterone, as reported previously (Kennedy et al., 1983b). PGE2 was reported to cause an increase in alkaline phosphatase activity in the stromal cells during decidualization via elevation of the cAMP level (Yee and Kennedy, 1991). This effect may be mediated by EP4. Thus, EP4 may mediate signals for decidualization of stromal cells.

The mRNA encoding EP3, which is coupled to the inhibition of adenylate cyclase, was specifically localized to the myometrium. Previous pharmacological studies demonstrated that PGE2 causes uterine contraction through elevation of the intracellular Ca^{2+} concentration (Goureau et al., 1992). Mouse EP3 expressed in CHO cells is coupled not only to the inhibition of adenylate cyclase, but also to Ca^{2+} mobilization via Gi (Irie et al., 1994). Therefore, PGE2-induced
uterine contraction may be mediated by an EP3-mediated Ca\textsuperscript{2+} signal in the myometrium.

As in the cases of EP\textsubscript{2} and EP\textsubscript{4}, the level of EP\textsubscript{3} expression also changed during pseudopregnancy; EP\textsubscript{3} expression was low on day 0, but increased to reach a maximal level on day 5. The temporal changes in EP\textsubscript{3} expression coincided well with the change in myometrial activity in pregnant and pseudopregnant rats; the myometrial activity was reported to increase after mating and reached a maximal level on day 5 (Crane and Martin, 1991a). Therefore, the level of EP\textsubscript{3} expression might affect myometrial activity. The cell populations expressing EP\textsubscript{3} also changed in a temporally specific manner; EP\textsubscript{3} transcripts were localized to the longitudinal smooth muscle on day 0, but expression was confined to the circular smooth muscle on day 5. To date, there have been no reports concerning changes in PGE\textsubscript{2}-induced myometrial contractility in these two distinct types of smooth muscle during pregnancy or pseudopregnancy. However, EP\textsubscript{3} expressed in the longitudinal smooth muscle on day 0 might be involved in longitudinal contraction observed during the periovulatory period (Crane and Martin, 1991b). EP\textsubscript{3}-mediated longitudinal contraction might contribute to sperm transport (Chalubinski et al., 1993). On the other hand, EP\textsubscript{3} highly expressed in the circular smooth muscle on day 5 might be involved in circular contraction necessary for retention and spacing of embryos (Crane et al., 1991a). At present, there is no information regarding the mechanism underlying such time-dependent changes in the expression of EP\textsubscript{3} mRNA in two distinct types of smooth muscle cells. More detailed analyses are therefore required.

In summary, the results presented here indicate distinct cellular localizations and time-dependent changes in the expression levels of PGE receptor subtypes in mouse uteri during pseudopregnancy. It is
also suggested that PGE2 modulates uterine functions through at least three receptors; EP2 is involved in blastocyst implantation signaling, EP4 is involved in decidual transformation of stromal cells, and EP3 is involved in regulation of myometrial contractility (Table 3).

ABSTRACT

Genomic DNA clones for the mouse PGE receptor subtype EP2 were isolated and characterized. The mouse EP2 gene is composed of 2 exons and 1 intron, and spans 16 kb. The intron which is approximately 12 kb in length is located at the end of the sixth transmembrane domain, as with other prostanoid receptor genes. Based on this structure, transcripts were analyzed in endotoxin-treated macrophages and pseudopregnant mouse uteri, in which abundant expression of EP2 mRNA was observed. Sequence analysis of cDNA clones from these origins and Northern hybridization of these RNAs revealed that the uterine EP2 mRNA (U-type) has a longer 5'-untranslated region than the macrophage EP2 transcript (M-type). The major transcription initiation sites for M-type and U-type EP2 are located 124 bp and 769 bp upstream of the translation start site, respectively. The M-type was expressed in various tissues, whereas the U-type was found only in the uterus. The 2 kb segment containing the immediate 5'-flanking and 5'-noncoding regions contain three consensus sequences for the NF-IL6 binding site, one consensus sequence for the NF-κB binding site, four AP-2 consensus sequences, one AP-4 consensus sequence, one potential cAMP response element, and one potential progesterone response element. These results suggest that EP2 gene expression in the macrophage and uterus is under the control of distinct mechanisms involving alternative promoters.
RESULTS

Structure of the mouse EP2 gene

Structural analysis of isolated clones revealed that the mouse EP2 gene spans 16 kb in length and contains 2 exons (Fig. 3-1). Exon 1 is composed of the 5'-untranslated region and the coding region from ATG to the putative sixth transmembrane domain of the receptor. Exon 2 encodes the residual part of the coding region and the 3'-untranslated region. The sequences of the exons were in complete agreement with that of the cDNA. The exon/intron boundaries conform perfectly with the GT/AG rule (Table 4) (Breathnach and Chambon, 1981; Mount, 1982). In Southern blot analysis of mouse genomic DNA, digestion by BamHI, NcoI, NdeI, or ScaI yielded a single hybridization band, suggesting that the EP2 is specified by a single gene (data not shown). Using the genomic DNA structure as a basis, the mRNA species from the macrophage and uterus were further characterized.

The noncoding regions are represented by open boxes, the putative transmembrane regions are indicated by hatched boxes and numbered, and the other coding regions are shown by closed boxes. The translation initiation site, AUG, the translation termination site, UGA, and two polyadenylation sites are indicated. Positions of probes used in the Northern blot analysis are depicted by bold bars and labelled. b, A diagram of the mouse EP2 gene. The restriction sites are indicated as follows: AatI (A), EcoRI (E), KpnI (K), SmaI (S). Exons are represented by open boxes.
Characterization of cDNAs from a mouse uterus library

As described in Chapter 1, the 2.2 kb species of EP2 mRNA was distributed in various tissues, whereas the 2.8 kb transcript was abundantly expressed only in the uterus, and hence appeared to be uterus-specific (Katsuyama et al., 1995). To obtain structural information on the uterus-derived EP2 transcript, EP2 cDNA clones were isolated from a mouse uterus cDNA library. Thirteen positive clones were isolated, and 9 clones contained the full-length of the coding region. Restriction analysis of these clones revealed that the sequence of the coding region was the same as that of ML202, a representative EP2 cDNA clone derived from the lung (Katsuyama et al., 1995). However, 5 out of 9 uterine clones contained an additional upstream genomic sequence (640 - 545 bp in length) at their 5'-ends compared with the lung cDNAs (Figs. 3-1 and 2). Due to these findings, it was further examined whether the additional sequence observed only in the uterine EP2 cDNA corresponds to the extra sequence in the uterine-specific 2.8 kb transcript.
Fig. 3-2. Nucleotide sequence of the 5'-flanking and 5'-noncoding regions of the mouse EP2 gene. Numbers on the left are relative to the adenosine in the ATG start codon. Representative cDNA clones ML202 and MU14 start at positions -145 and -743, respectively. The major transcription initiation sites for macrophage (M-type) and uterine (U-type) transcripts are indicated. Two other potential transcription start sites for macrophage transcripts are shown by open triangles. Potential binding sites for the indicated transcription factors are underlined. The two XbaI restriction sites are italicized and underlined. Locations of the primers used in primer extension analysis are shown by lines above the sequence.
Northern hybridization with region-specific probes

The preliminary investigation showed that the expression of the 2.2 kb EP2 transcript was higher in LPS-treated J774.1 cells, a macrophage-like cell line, than in the lung. To examine whether the uterus-specific 2.8 kb transcript is derived due to a difference in the length of the 5'-noncoding sequence, Northern blot analysis was performed on the J774.1 cells and uteri using a probe specific for the additional sequence. First a HincII fragment covering the seventh transmembrane and C-terminal regions of EP2 was used as a probe (Fig. 3-1). As shown in Fig. 3-3a, a major band was observed at 2.2 kb and 2.8 kb in LPS-treated J774.1 cells and pseudopregnant day 5 uteri, respectively. In J774.1 cells, a minor band was also observed at 4.0 kb. On the other hand, when a XbaI fragment specific for uterine EP2 cDNA was used as a probe (Fig. 3-1), the 2.2 kb transcript from the J774.1 cells was not detected (Fig. 3-3b). These results showed that only the uterine EP2 transcript has an additional 5'-untranslated region, suggesting that the transcription of the uterine EP2 mRNA starts approximately 600 bp upstream of that in the lung.
Fig. 3-3. Northern blot analysis of RNAs isolated from LPS-treated J774.1 cells and pseudopregnant day 5 mouse uteri. LPS-treatment of J774.1 cells and achievement of pseudopregnancy in virgin mice were performed as described in "EXPERIMENTAL PROCEDURES." Total RNA (10 μg) was applied to each lane. a, EP₂ mRNAs were detected by a 543 bp-HincII fragment covering the seventh transmembrane and C-terminal regions. A major band was detected at 2.2 kb and 2.8 kb in J774.1 cells and uteri, respectively. b, A 469 bp-XbaI fragment from the 5'-noncoding region of uterine EP₂ cDNA was used as a probe. Only the 2.8 kb transcript was detected. J, LPS-treated J774.1 cells; U, pseudopregnant day 5 uteri.
Determination of the transcription start site

In order to confirm uterus-specific transcription initiation, the transcription initiation sites for the macrophage (M-type) and uterus (U-type) EP2 transcripts were investigated. Primer extension analysis was first performed with two antisense oligonucleotides, EP2NR (corresponding to position +27 - -3) and EP2UR (position -610 - -644) (Fig. 3-2). When EP2NR was used as a primer, an extended product was detected in RNA from J774.1 cells, which started at the guanine nucleotide at position -124 (Fig. 3-4a). The product was not detected in RNA from the uterus. As shown in Fig. 3-4b, when EP2UR was used as a primer, an extended product was detected in RNA from the uterus, which started at the guanine nucleotide at position -769. This product was barely detected in RNA from J774.1 cells. Thus, the major transcription initiation sites for M-type and U-type EP2 were identified as positions -124 and -769, respectively. Two additional minor transcription initiation sites for the M-type were further identified by the 5'-RACE experiment (Fig. 3-2). From these results it is concluded that the transcription start site of uterine EP2 mRNA is approximately 600 bp upstream of that in the other tissues.
Fig. 3-4. Determination of the transcription start sites of the mouse EP2 gene by primer extension analysis. $^{32}$P-labeled antisense oligonucleotides were annealed to poly (A)$^+$ RNAs as described in "EXPERIMENTAL PROCEDURES." a and b, Extension by EP2NR and EP2UR primers, respectively. Arrowheads indicate the extended products. J, LPS-treated J774.1 cells; U, pseudopregnant day 5 uteri.
Diversity of the EP2 transcripts in their 3'-noncoding region

Heterogeneity was also found in the length of the 3'-noncoding sequence in EP2 cDNA (Figs. 3-1 and 5). When cloning the EP2 cDNA from a mouse lung library, isolated clones were subdivided into three groups, represented by ML202, ML203, and ML204, according to their 3'-terminal lengths. Eleven out of 12 clones from the uterus library had the same 3'-tail as ML203, suggesting that this type of 3'-terminal structure is the dominant form in the uterus (Fig. 3-5, 3'-short form). The other clone, MU6, had the same 3'-tail structure as ML204 (Fig. 3-5, 3'-long form). This mRNA species contained not only three polyadenylation signals, AATAAA (Manley et al., 1985), but also five mRNA destabilizing motifs, ATTTA (Malter, 1989). To examine whether the 4.0 kb minor band detected in J774.1 cells corresponds to the 3'-long form, Northern hybridization was performed with a probe specific for the 3'-long form. However, significant levels of transcripts were not detected with this probe (data not shown), suggesting that the 3'-long form was expressed at a very low level, or was susceptible to degradation. The 4.0 kb minor band detected in J774.1 cells might be an immature form of the 2.2 kb mRNA.
Fig. 3-5. Nucleotide sequence of exon 2 of the mouse EP2 gene. The deduced amino acid sequence is shown beneath the nucleotide sequence using the single-letter code. The positions of the putative transmembrane segments, VI and VII, are underlined. AATAAA polyadenylation signals are double underlined. ATTAA mRNA destabilizing motifs are italicized and underlined. The previously reported cDNA clone ML202 stopped at nucleotide 724 and was polyadenylated.
Tissue distribution analysis of EP2 mRNA variants

Tissue specificity of the expression of EP2 mRNA with a long 5'- or 3'-untranslated region was examined by RT-PCR (Fig. 3-6). As for the 5'-end variants, when the MG2721 primer, which amplifies both the M-type and U-type EP2 was used, a 977 bp fragment was detected in all tissues examined. In contrast, when amplified with the MG2723 primer specific for the U-type, a 1334 bp fragment was detected only in pseudopregnant day 5 uteri (Fig. 3-6b). These results suggest that the M-type was expressed in various tissues, whereas the U-type was expressed exclusively in the uterus. As for the 3'-end variants, the long form was expressed in all tissues examined (Fig. 3-6c), suggesting that tissue specificity does not exist in the expression of the EP2 mRNA with the long 3'-untranslated region.
Fig. 3-6. Tissue specificity of EP2 mRNA variants. RT-PCR was performed as described in "EXPERIMENTAL PROCEDURES." a, Diagram of the locations of the PCR primers and amplified products. The MG2721 primer in combination with the EP2EXR primer amplifies both the M-type and U-type EP2 transcripts, and a 977 bp fragment is detected. On the other hand, the MG2723 primer amplifies only the U-type mRNA and a 1334 bp fragment is detected. As for the 3'-end variants, the EP2MJR primer in combination with the EP2EXF primer amplifies both the 3'-short form and the 3'-long form, and a 899 bp fragment is detected. On the other hand, the ML204R4 primer amplifies only the 3'-long form, and a 1019 bp fragment is detected. b, Distribution of the two types of 5'-end variants. A uterine EP2 cDNA clone was used as a control of the amplification. The M-type transcript is expressed in various tissues, whereas the expression of U-type mRNA is restricted to the uterus. c, Distribution of two forms of 3'-end variants. ML204 was used as a control of the amplification. The long form is expressed in all tissues examined. C, control DNA; T, thymus; Lu, lung; Li, liver; S, spleen; I, ileum; U, pseudopregnant-day-5 uterus.
**Analysis of the promoter sequence**

The 2 kb nucleotide sequence containing the immediate 5' flanking and 5'-noncoding regions of the mouse EP2 gene was examined (Fig. 3-2). No consensus TATA-box sequence was found in the presumed promoter region of either the M-type or U-type EP2. Although one consensus TATA-box sequence is present at position -1603, it seems too distant to be involved in transcription. A CCAAT-box is present 247 bp upstream of the major transcription start site for the U-type. Consensus motifs relevant to LPS stimulation, such as NF-IL6 and NF-κB binding sites, are found in the 5'-flanking region. Consensus sequences for the NF-IL6 binding site are present at positions -811, -1593, and -1871. One consensus sequence for the NF-κB binding site is found at position -1982. In addition, in the promoter region for the M-type, one putative cAMP response element (CRE) and a cluster of three AP-2 consensus sequences were found at positions -480 and -352, -353, and -359, respectively. On the contrary, no apparent consensus sequence related to hormone-dependent expression in the uterus, such as an estrogen response element (ERE) or a progesterone response element (PRE), was found in the 5'-flanking region. However, one potential PRE was found at position -844, 75 bp upstream of the major transcription start site for the U-type. In addition, one AP-2 consensus sequence and one AP-4 consensus sequence are present at positions -1295 and -1370, respectively.
DISCUSSION

Although both EP2 and EP4 are coupled to the stimulation of adenylate cyclase, expression of EP2 mRNA is much lower than that of EP4 in almost all tissues. However, abundant EP2 mRNA expression was observed in the macrophage and uterus. As described in Chapter 2, EP2 mRNA is induced in the luminal epithelium of the mouse uterus on day 5 of pseudopregnancy, suggesting that the EP2 gene is hormonally regulated in the uterus (Katsuyama et al., 1997). The dominant EP2 transcript detected in the uterus was 2.8 kb in length. On the other hand, EP2 mRNA in J774.1 cells, a macrophage-like cell line, is highly induced by stimulation with LPS (unpublished data). In this cell line, the major EP2 transcript detected was 2.2 kb in length, as was observed in tissues other than the uterus. These observations lead to the hypothesis that expression of EP2 is induced by hormonal or pathophysiological stimuli, and that distinct activation systems of EP2 gene expression exist in these two types of stimuli. As an initial step to clarify the mechanisms of EP2 induction, genomic DNA clones encoding EP2 were isolated and characterized. As a result, differences were found in transcription initiation of the EP2 gene between the macrophage and uterus.

The mouse EP2 gene is composed of 2 exons. Exon 1 contains the 5'-untranslated region, the translation initiation codon, and most of the EP2 receptor coding region. Intron 1, which is approximately 12 kb in length, divides the coding region at the putative sixth transmembrane domain. The location of this intron in the sixth transmembrane domain is completely conserved in the genes of eight types and subtypes of prostanoid receptors (Nüsing et al., 1993; Hirata et al., 1994; Bátshake et al., 1995; Ogawa et al., 1995; Arakawa et al., 1996; Kotani et al.,
1997; Hasumoto et al., 1997). On the other hand, the EP2 gene does not have an intron in the 5'-noncoding region, which was found to be present in the genes of five types of prostanoid receptors. Among the prostanoid receptors, the human TP receptor gene and the bovine FP receptor gene have been reported to generate two mRNA species by alternative promoter usage (Nüsing et al., 1993; Ezashi et al., 1997). However, these two mRNA species appeared to be co-expressed in the same tissue. In the present study, diversity of EP2 mRNA was identified in both the 5'- and 3'-ends. RT-PCR and Northern analyses revealed that the 3'-end variants, the short form and the long form (Fig. 3-5), are co-expressed in various tissues and that the short form is dominant. On the other hand, expression of the 5'-end variants (Fig. 3-2) is tissue-specific; 5'-long (U-type) mRNA is expressed only in the uterus and 5'-short (M-type) mRNA is expressed in other tissues and the macrophage. Thus, the EP2 gene performs tissue-specific transcriptional initiation. The significance of the long 5'-noncoding sequence of the U-type is yet unknown, but it might be involved in the alteration of the stability or translation efficiency of the transcript. Indeed, the 5'-noncoding region of the U-type contains four AUG codons. Presence of these start codons upstream of the main open reading frame is known to inhibit cap-dependent translation (Kozak, 1991). Therefore, the translation efficiency of the U-type might be lower than that of the M-type. Strict control of translation, in addition to transcriptional regulation, might be necessary for precise expression of EP2 in the uterus.

As described in Chapter 2, it was found that in the synchronized mouse uterus, EP2 mRNA expression is induced in the luminal epithelial (LE) cells only during the periimplantation period (Katsuyama et al., 1997). This observation suggests the involvement of PGE2 and the EP2 receptor in blastocyst implantation. Furthermore, preliminary analyses
using ovariectomized mice revealed that the expression of EP2 mRNA was induced in uterine LE cells by exogenously-added progesterone (unpublished data). These results suggest that uterine expression of the EP2 gene is under the control of ovarian progesterone. In fact, there is one potential PRE in the 5'-flanking sequence, 75 bp upstream of the uterine transcription start site. However, it is yet unknown whether this PRE works as an uterus-specific promoter in regulation of EP2 gene expression. All that is known is that uterine transcription of the EP2 gene starts 645 bp upstream of the transcription initiation site in the macrophage cell line. Therefore, one possible explanation is that the PRE in the EP2 gene may be involved in activation of the closer transcription start site in uterine LE cells in response to progesterone.

On the other hand, expression of the 2.2 kb species of the EP2 transcript was widely observed in various tissues. This EP2 transcript was induced by LPS-stimulation in J774.1 cells. PGE2 is known to inhibit LPS-induced cytokine production in the macrophage via cAMP accumulation (Zhong et al., 1995). LPS-induced EP2 might be involved in such inhibitory actions of PGE2 in the activated macrophage. Indeed, in the 2 kb immediate 5'-flanking region of the EP2 gene, three consensus sequences for the NF-IL6 binding site and one consensus sequence for the NF-κB binding site were found (Fig. 3-2). It is possible that the 2.2 kb transcript is induced by these inflammatory transcription factors (Akira and Kishimoto, 1992; Matsuoka et al., 1993). If this is the case, it seems reasonable that the expression levels of the 2.2 kb transcript were extremely low in healthy mouse tissues other than the uterus.

The most remarkable finding in this study is that uterine transcription initiation of the EP2 gene is different from that in other tissues. This suggests that distinct promoters are involved in EP2 gene

47
expression in the uterus and other tissues. Such tissue specific expression respondent to various physiological stimuli has been reported in the mouse FP receptor gene; the 7.3 kb fragment of the 5'-flanking region of the FP gene contains enough promoter sequence for its expression in the stomach and kidney, but not in the corpora lutea (Hasumoto et al., 1997). In the case of the EP2 gene, however, it remains unknown at present whether the uterine promoter and the promoter for other tissues work independently from each other. It is also unclear whether some of the putative promoter regions in both systems overlap and share some basic transcription factors. Thus, further systematic studies on EP2 gene expression in the uterus and other tissues are essential.
CONCLUSION

The author performed a study on the structure and function of the prostaglandin E receptor subtype EP2. A summary of the results obtained here are as follows:

1. Expression of EP2 mRNA was much lower than that of EP4 in almost all tissues. EP2 mRNA was expressed most abundantly in the uterus.

2. The mRNAs for EP2, EP3, and EP4 showed distinct cellular localizations and time-dependent changes in the level of expression in individual cells in pseudopregnant mouse uteri. Confined expression of EP2 mRNA in the luminal epithelium on day 5 of pseudopregnancy suggests the involvement of PGE2 and the EP2 receptor in blastocyst implantation signaling (Fig. 4-1).

3. Transcriptional initiation of the EP2 gene in the uterus was different from that in other tissues and that in LPS-stimulated macrophages (Fig. 4-1).

Information obtained from the present study is bound to facilitate the understanding of the physiological functions of PGE2, as well as the development of more subtype-specific PGE2 analogues for therapeutic purposes.

EXPERIMENTAL PROCEDURES

Chapter 1

1. Materials

Butaprost, SC-19220 and misoprostol, M&B 28767, and sulprostone were generous gifts from Dr. P. J. Gardiner of Bayer U. K. Ltd., Dr. P. W. Collins of Searle, Dr. M. P. L. Caton of Rhone-Poulenc Ltd., and Schering, respectively. [5,6,8,9,11,12,14,15-3H]PGE2 (181 Ci/mmol), iloprost, and the 125I-labeled cyclic AMP assay system were obtained from Amersham Corp. [α-32P]dCTP (3,000 Ci/mmol), [α-32P]UTP (3,000 Ci/mmol), [α-35S]CTP (1,000 Ci/mmol), and [γ-32P]ATP (3,000 Ci/mmol) were obtained from Du Pont-New England Nuclear. PGE2, 11-deoxy PGE1, 19(R)OH-PGE2, 1-OH-PGE1, and 16,16-dimethyl PGE2 were purchased from Cayman Chemical (Ann Arbor, MI). PGE1, PGF2α, and PGD2 were obtained from Funakoshi Pharmaceuticals (Tokyo, Japan). Sources of other materials are shown in the text.

2. cDNA cloning of the mouse prostanoid EP2 receptor

2-1. Amplification of a cDNA Fragment of the Mouse EP2

First-strand cDNA was synthesized from mouse lung total RNA using random hexanucleotides as primers. Degenerate PCR primers, 5'-CTGGGATCCATGCTCATGCT(CG)TT(CT)GC(ACGT)ATGGC-3' and 5'-GCAGAATTCAGACGGCGAA(CG)GT(AG)AT(GT)GTCAT-3', corresponding to the putative third and sixth transmembrane domains of the human EP2 (Regan et al., 1994) were synthesized. The thermal cycle program was 2 cycles of 94℃ for 0.8 min, 48℃ for 1 min, and 72℃ for 3 min, 3 cycles of 94℃ for 0.8 min, 50℃ for 1 min, and 72℃ for 2 min, followed by 27 cycles of 94℃ for 0.8 min, 55℃ for 1 min, and 72℃
for 3 min. Amplified cDNAs were subcloned into pBluescript II SK(+) (Stratagene). A 466-base pair clone showed a sequence highly homologous to the human EP₂ receptor cDNA.

2-2. Isolation of a Functional cDNA Clone

A mouse lung cDNA library was prepared by the oligo(dT) priming method. Approximately $3.0 \times 10^5$ recombinant clones from this library were screened by hybridization with the cDNA fragment obtained by PCR. Hybridization was carried out at 68°C for 15 h in 6 × SSC (900 mM NaCl and 90 mM sodium citrate) containing 5 × Denhardt’s solution (0.1% Ficoll, 0.1% polyvinylpyrrolidone, and 0.1% bovine serum albumin) and 0.5% SDS, and filters were washed twice at 68°C for 30 min in 2 × SSC containing 1% SDS. Four positive clones were isolated, and a representative clone, ML202, was subjected to sequence and expression analyses. Nucleotide sequencing was carried out on both strands by the dideoxy chain termination method.

3. Stable Expression in CHO Cells

The EcoRI insert of ML202 was subcloned into pdKCR-dhfr (Oikawa et al., 1989), and the resultant plasmid DNA was transfected into CHO cells deficient in dihydrofolate reductase activity (CHO-dhfr⁻) by the lipofection method (Felgner et al., 1987). Cell populations expressing the cDNA together with dihydrofolate reductase were selected in α-modification of Eagle’s medium lacking ribonucleosides and deoxyribonucleosides and containing penicillin (100 units/ml), streptomycin (100 μg/ml), and 10% dialyzed fetal bovine serum (Cell Culture Laboratory). From these cell populations, clonal cell lines were isolated by single-cell cloning. Expression of the mouse cDNA was assessed by Northern blot analysis.

52
4. **Ligand Binding Assay**

Using the crude membrane fraction (300,000 x g pellet fraction) prepared from a CHO cell clone expressing the receptor, [³H]PGE₂ binding was determined as described by Nishigaki et al. (1995). The membrane (40 μg) was incubated with 4 nM [³H]PGE₂ (397,000 dpm) at 30°C for 1 h in 100 μl of buffer A (20 mM HEPES-NaOH, pH 7.4, 1 mM EDTA, 10 mM MgCl₂). The reaction was terminated by the addition of ice-cold buffer A, and the resultant mixture was immediately filtrated through Whatman GF/C filter. The filter was then washed twice with 3 ml of ice-cold buffer A, and the radioactivity associated with the filter was measured by a liquid scintillation counter. Non-specific binding was determined using a 1,000-fold excess of unlabeled PGE₂ in the reaction mixture. The specific binding was calculated by subtracting the non-specific binding from the total binding.

5. **Measurement of cAMP Formation**

The cAMP levels in the CHO cell clone were measured as described by Nishigaki et al. (1995). The cells cultured in 24-well plates (5 x 10⁵ cells/well) were incubated at 37°C for 10 min in HEPES-buffered saline (140 mM NaCl, 4.7 mM KCl, 2.2 mM CaCl₂, 1.2 mM MgCl₂, 1.2 mM KH₂PO₄, 11 mM glucose, and 15 mM HEPES, pH 7.4). Reactions were started by the addition of the test agents along with 100 μM Ro-20-1724. After incubation at 37°C for 10 min, reactions were terminated by the addition of 10% trichloroacetic acid. The cAMP formed was measured by the radioimmunoassay kit.

6. **Northern Blot Analysis**

Total RNAs from various mouse tissues were isolated by the acid guanidinium thiocyanate-phenol-chloroform method (Chomczynski and
Sacchi, 1987), and poly(A)+ RNAs were purified using Oligotex dT30 <Super> (Takara Shuzo, Kyoto, Japan). For the detection of EP2 transcripts, 5 µg of poly(A)+ RNAs purified twice with the Oligotex from various tissues were separated by electrophoresis on a 1.5% agarose gel, and transferred onto a nylon membrane (Hybond-N, Amersham). An antisense RNA probe was synthesized with T7 RNA polymerase using linearized ML202 as the template. For the detection of the EP4 mRNA, 5 µg of poly(A)+-rich RNA (purified once with the Oligotex) was used. An antisense RNA probe was synthesized with T7 RNA polymerase using linearized MP412 with the XhoI fragment deleted as the template. Hybridization was carried out at 70°C for 4 hr in 5 x SSC, 50% formamide, 5 x Denhardt's solution, 0.2% SDS, 0.05 M sodium phosphate (pH 6.5), 250 µg/ml heat-denatured salmon sperm DNA, 200 µg/ml yeast transfer RNA, and the 32P-labeled probe. Filters were washed at 70°C in 2 x SSC and 1% SDS for 10 min, in 0.2 x SSC and 0.5% SDS for the next 10 min, and then in 0.1 x SSC and 0.1% SDS for 20 min. The filter for detecting the EP4 mRNA was treated with 1 µg/ml RNaseA at 20°C for 10 min, and washed again at 70°C in 0.1 x SSC and 0.1% SDS for 10 min.

Chapter 2

1. Treatment of Animals

ddY mice were purchased from Japan SLC Inc. (Hamamatsu, Japan). Pseudopregnancy was achieved in virgin mice as follows. Immature (21-day-old) female mice were obtained and housed under a 12-h light, 12-h dark photoperiod, with lights on at 0800 h. The mice received a single ip injection of 5 IU PMSG. After 48 h, mice were injected ip with 5 IU hCG and paired overnight with a vasectomized male of the same inbred line. The morning on which a vaginal plug was
detected was taken as day 0.5 of pseudopregnancy. Mice were killed at different intervals after mating, and the uteri were isolated, frozen immediately in liquid nitrogen (for RNA isolation) or in 2-methylbutane at -50°C (for preparation of uterine sections), and stored at -80°C until use. For RNA isolation, uteri were collected from three mice for each day of pseudopregnancy studied, and Northern blot experiments were independently repeated three times. In situ hybridizations were repeated twice or three times for each day of pseudopregnancy studied.

2. Hybridization Probes

Mouse cDNAs for EP1, EP2, EP3, and EP4 were subcloned into pBluescript II (Stratagene, La Jolla, CA) for synthesis of both sense and antisense cRNA probes (Sugimoto et al., 1992; Honda et al., 1993; Watabe et al., 1993; Katsuyama et al., 1995). For Northern hybridization, antisense 32P-labeled cRNA probes were generated, whereas for in situ hybridization, sense and antisense 35S-labeled cRNA probes were generated using the appropriate polymerases. Cold antisense riboprobes were also synthesized by the same procedure with unlabeled nucleotides.

3. Northern Blot Analysis

Uteri were collected from three mice for each day of pseudopregnancy studied. Uterine total RNAs were isolated as described above. Total RNA (15 µg) was separated by electrophoresis on a 1.5% agarose gel and transferred onto a nylon membrane (Hybond-N, Amersham). Four different blots were prepared and separately hybridized with 32P-labeled probes for EP1, EP2, EP3, and EP4. Hybridization was carried out essentially as described above. After hybridization, the blots were washed under stringent conditions, and the
hybrids were detected by autoradiography. Then the blots were stripped and rehybridized with $^{32}$P-labeled DNA probe for glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Hybridization was carried out at 68°C in 6 × SSC, and filters were washed at 68°C in 2 × SSC as described above. Autoradiograms were subjected to densitometric scanning (AE-6900M, ATTO, Tokyo, Japan) for quantitation of PGE receptor mRNA levels relative to GAPDH mRNA levels. Northern blot experiments were independently repeated three times, and similar results were obtained. Representative results are shown in Fig. 2-1.

4. Preparation of Uterine Sections

Uterine sections 10 µm thick were cut on a Jung Frigocut 2800E cryostat and mounted onto poly-L-lysine-coated glass slides. The sections were fixed in 4% formalin in PBS for 10 min, rinsed in PBS, and acetylated with 0.25% acetic anhydride in 0.1 M triethanolamine-0.9% NaCl for 10 min at room temperature. After dehydration sequentially in 70%, 95%, and 100% ethanol, the sections were air-dried and stored at -80°C until use.

5. In Situ Hybridization

Riboprobes were prepared essentially as described above by transcription in the presence of [$\alpha$-35S]CTP to specific activities of 1.0 × 10⁹ cpm/µg. After removing unincorporated nucleotides, riboprobes were degraded to about 150 bases by alkaline hydrolysis. Hybridization was carried out essentially as described by Sugimoto et al. (1994b). The specificity of the signal with each antisense probe was verified either by its disappearance with the addition of an excess of unlabeled probe (shown for EP3 in Fig. 2-4f, not shown for others), or by absence of
specific hybridization with sense probes (data not shown). Hybridized sections were dipped in nuclear track emulsion (NTB3, Eastman Kodak, Rochester, NY) diluted 1:1 with water. After exposure for about 4 weeks at 4°C, the dipped slides were developed and fixed, then counterstained with hematoxylin and eosin. These experiments were repeated twice or three times on each day of pseudopregnancy studied.

Chapter 3
1. Isolation of genomic clones

A mouse genomic library (approximately 5.0×10⁵ recombinants from the 129SVJ λFIXII library, Stratagene) was screened by hybridization with a 466 bp fragment of the mouse EP₂ cDNA spanning the putative third to sixth transmembrane domains. Hybridization was carried out under the conditions described above. Ten positive clones were isolated and subjected to sequence and restriction analyses. These clones contained the nucleotide sequence upstream of the sixth transmembrane domain of the mouse EP₂ but not the seventh transmembrane and 3'-untranslated regions. Therefore, the library was then screened with a 543 bp-HincII fragment covering the putative seventh transmembrane and C-terminal regions. Five other genomic clones were isolated and subjected to sequence and restriction analyses. Nucleotide sequencing was carried out on both strands by the dideoxy chain termination method. Intron size was determined by PCR using mouse liver genomic DNA as the template and the LA PCR Kit Ver. 2 (Takara Shuzo, Kyoto, Japan). Oligonucleotides (35-mer) corresponding to the exon-intron junctions of the EP₂ gene were used as PCR primers, and amplification was performed under these conditions in the following order; (1) 94°C for 1 min, (2) 98°C for 10 sec and 68°C for 15 min for 14 cycles, (3) 98°C for 10 sec and 68°C for 15
min, with an addition of 15 sec/cycle at 68°C for 16 cycles, (4) 72°C for 10 min. The amplified DNA fragment was subjected to restriction analysis.

2. Isolation of cDNA clones from a mouse uterus cDNA library

A mouse uterus cDNA library was prepared by the oligo(dT)-priming method. Approximately 4.0×10⁵ recombinant clones from this library were screened by hybridization with the insert DNA of ML202 (Katsuyama et al., 1995). Thirteen positive clones were isolated and subjected to sequence and restriction analyses.

3. Northern Blot Analysis

J774.1 macrophage-like cells were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum, penicillin (100 units/ml), and streptomycin (100 µg/ml). The cells were treated with 100 ng/ml LPS (B. E. coli 055:B5, Difco Laboratories, Detroit, MI) for 3 hr. Pseudopregnancy was achieved in virgin mice essentially as described above. Total RNA was isolated from LPS-treated J774.1 cells and pseudopregnant day 5 uteri as described above. The RNAs (10 µg) were separated by electrophoresis on a 1.5% agarose gel, and transferred onto a nylon membrane (BIODYNE, Pall Biosupport Division, East Hills, NY). Hybridization probes used were as follows; a HindIII fragment (543 bp) covering the seventh transmembrane and C-terminal regions, a XbaI fragment (469 bp) corresponding to the 5'-noncoding region of uterine EP₂ cDNA clones, and an EcoRI/SphI fragment (377 bp) of the 3'-terminus of an EP₂ cDNA clone with a long 3'-untranslated region (ML204). Hybridization was carried out under the conditions described above.
4. Determination of the transcription start sites

The two antisense oligonucleotides used in primer extension analysis were the EP2NR primer corresponding to nucleotides +27 to –3 of ML202 (Katsuyama et al., 1995) and the EP2UR primer corresponding to 610-644 bp upstream of the ATG start codon. The primers were labeled with [γ-32P]ATP (Du Pont-New England Nuclear) by T4 polynucleotide kinase. Poly(A)+ RNAs were purified from LPS-treated J774.1 cells and pseudopregnant day 5 uteri using Oligotex dT30 <Super> (Takara Shuzo, Kyoto, Japan). The 32P-labeled EP2NR primer was annealed overnight to 5 μg of poly(A)+ RNAs in hybridization buffer (40 mM PIPES, pH 6.4, 1 mM EDTA, 0.4 M NaCl, 80% formamide) at 30°C. The 32P-labeled EP2UR primer was annealed to 10 μg of poly(A)+ RNAs. The annealed RNA/primer mixture was extended by Superscript II reverse transcriptase (Life Technologies) at 42°C for 1 h. The extension products were electrophoresed on a 6% polyacrylamide gel containing 7 M urea. Resultant fragment sizes were determined by sequencing ladders generated by the same primers.

The 5'-RACE experiment was performed essentially as described by Hasumoto et al. (1997). Poly(A)+ RNA (1 μg) from LPS-treated J774.1 cells was reverse transcribed with the EP2NR primer, and the resultant first strand cDNA was polyadenylated by terminal deoxynucleotidyl transferase. The cDNA was amplified with an oligo(dT) primer (25-mer) and the EP2NR3 primer complementary to nucleotides 96 - 125 of ML202. The resultant products were then amplified using another primer, EP2NR4, complementary to nucleotides 71 - 95 of ML202. The amplified products were separated on a 2% agarose gel, and two major products, approximately 350 bp and 270 bp in length, were subcloned into a plasmid vector for sequencing.
5. Detection of EP2 mRNA variants by RT-PCR

Total RNAs from various tissues were transcribed with M-MLV reverse transcriptase (Life Technologies) using hexanucleotides as primers, and the resultant cDNAs were used for PCR. For the detection of 5'-end variants, amplification was performed with the EP2EXR primer complementary to the 35 nucleotides at the 5'-terminus of exon 2, in combination with either the MG2721 primer corresponding to nucleotides –99 - –72 or the MG2723 primer corresponding to nucleotides –456 - –429. A uterine EP2 cDNA clone (MU14) was used as a positive control of the amplification. For the amplification of 3'-end variants, PCR was performed with the EP2EXF primer corresponding to the 35 nucleotides at the 3'-terminus of exon 1, in combination with either the EP2MJR primer complementary to nucleotides 840 - 864 of exon 2 or the ML204R4 primer complementary to nucleotides 955 - 984 of exon 2. ML204 was used as a positive control of the amplification. Amplified products were separated by electrophoresis on 1% agarose gels.
ACKNOWLEDGMENTS

The author wishes to express his sincere appreciation to Professor Atsushi Ichikawa, Graduate School of Pharmaceutical Sciences, Kyoto University, for his stimulating guidance and encouragement through the course of this work.

The author's heartfelt appreciation is given to Associate Professor Yukihiko Sugimoto, Graduate School of Pharmaceutical Sciences, Kyoto University, for his immediate guidance and encouragement. Appreciation is also given to Professor Manabu Negishi, Graduate School of Pharmaceutical Sciences, Kyoto University, for his fruitful suggestions.

Thanks are also given to Associate Professor Manabu Fukumoto, Dr. Keiko Takabatake, and Professor Shuh Narumiya, Graduate School of Medicine, Kyoto University, for their valuable advice and discussions.

The author is grateful to Dr. Nobuhiro Nishigaki, M.Sc. Kimiko Morimoto, and Dr. Ken-yuh Hasumoto, Graduate School of Pharmaceutical Sciences, Kyoto University, for their continuous encouragement, helpful discussions, and technical support.

The author also thanks members of the Department of Physiological Chemistry, Graduate School of Pharmaceutical Sciences, Kyoto University, for their encouragement.
