The Magnetic Properties of Ni(OH)\textsubscript{2} and \(\beta\)-Co(OH)\textsubscript{2}

Hiroki MIYAMOTO*

(Takada Laboratory)

Received August 30, 1966

The magnetic properties of Ni(OH)\textsubscript{2} and \(\beta\)-Co(OH)\textsubscript{2} which have cadmium iodide type structure were experimentally studied by measurements of temperature dependence of magnetic susceptibility and magnetic field dependence of magnetization.

In the case of Ni(OH)\textsubscript{2}, sample, where the c-axis of each particle is oriented in the same direction, was prepared to determine the direction of spin axis.

The results obtained are as the following.

1. At temperatures below 30°K, Ni(OH)\textsubscript{2} was antiferromagnetic and the spin axis was directed in parallel to the c-axis. The susceptibility well above the Néel temperature obeyed the Curie-Weiss law with a positive paramagnetic Curie point (35°K). Effective Bohr magneton number was deduced to be 3.2 \(\mu_B\). At 4.2°K, the magnetization \(M_\text{f}\), measured when the magnetic field was parallel to the c-axis of oriented Ni(OH)\textsubscript{2} powder, abruptly increased in the magnetic field about 55 KOe and was saturated by the field above 85 KOe. These phenomena allow to conclude that Ni(OH)\textsubscript{2} is metamagnetic; the magnetic moments within a metal ion layer form a ferromagnetic sheet and the moments in adjacent layers are antiparallel, such as in the case of FeCl\textsubscript{2}.

2. \(\beta\)-Co(OH)\textsubscript{2} exhibited an antiferromagnetic behavior below 12.3°K. The susceptibility above 100°K also obeyed the Curie-Weiss law with a positive paramagnetic point (20°K). Effective Bohr magneton number was obtained to be 5.2 \(\mu_B\). At 4.2°K, the magnetization gradually increased with increasing magnetic field until it was saturated by the field of about 35 KOe. From these phenomena the metamagnetic behaviors of \(\beta\)-Co(OH)\textsubscript{2} were made clear. In this case, it is suggested that the anisotropic field is smaller than the antiferromagnetic internal field and that the spin axis lies in the c-plane.

I. INTRODUCTION

The present paper deals with magnetic properties and magnetic structures of Ni(OH)\textsubscript{2} and \(\beta\)-Co(OH)\textsubscript{2}.

Ni(OH)\textsubscript{2} and \(\beta\)-Co(OH)\textsubscript{2} have a hexagonal layer structure of CdI\textsubscript{2} type which consists of metal ions separated by two layers of OH ions.

The anhydrous dichlorides of iron, nickel and cobalt, which also have a CdCl\textsubscript{2} type structure, have antiferromagnetic spin structures\textsuperscript{12}. In the antiferromagnetic state, the magnetic moments of metal ions within a layer are strongly coupled ferromagnetically, while the moments in adjacent layers are weakly coupled antiparallel. Because of this characteristic magnetic structure, these chlorides of iron group exhibit an unusual magnetic behavior called “Metamagnetism”.

In contrast with an usual antiferromagnet, the magnetic susceptibility at the

The Magnetic Properties of Ni(OH)$_2$ and $\beta$-Co(OH)$_2$

temperature well above the transition point obeys the Curie-Weiss law $\chi=C/T-T_0$ with a positive paramagnetic Curie point ($T_0$), because the ferromagnetic internal field is stronger than the antiferromagnetic internal field. For magnetization, FeCl$_2$ which is antiferromagnetic below $T_N$($25^\circ$K) shows the transition from antiferromagnet to ferromagnet by the application of the external magnetic field of 11 KOe at $4.2^\circ$K. This transition was observed by the sudden increase of the magnetization. Magnetizations of CoCl$_2$ and NiCl$_2$ do not show such a behavior as that of FeCl$_2$ but show the gradual increase with increasing magnetic field.

This phenomenon of "Metamagnetism" was theoretically explained by Kamomori.

The anisotropy field $H_A$ of FeCl$_2$, of which the spin axis is parallel to the c-axis, is much larger than the antiferromagnetic internal field $H_E$. Therefore, when the external field is applied in parallel to the c-axis, antiferromagnetic FeCl$_2$ can directly change to ferromagnetic FeCl$_2$ before the external field reaches the antiferromagnetic critical field $H_c'=\sqrt{\frac{2H_AH_E}{H_A+H_E}}$.

In the cases of CoCl$_2$ and NiCl$_2$, where spin axis lies in the c-plane and $H_A$ is much smaller than $H_E$, the spin direction changes to be perpendicular to the magnetic field before the transition from antiferromagnetic to ferromagnetic occurs, when the field is applied in perpendicular to the c-axis. When the magnetic field higher than $H_c'$ is applied, the magnetization increases linearly inclined at $\chi_\perp$ till it is saturated by the field equal to 2$H_E$. When magnetic field is applied in parallel to the c-axis, the magnetization increases linearly inclined at $\chi_\perp$ with increasing field. Therefore, the magnetization curves of powder sample of CoCl$_2$ and NiCl$_2$ consist of the mixture of the curves of parallel and perpendicular magnetization.

Considering the crystallographic analogy between hydroxides and anhydrous chlorides of iron group, hydroxides were expected to show a metamagnetic property.

In the present paper, susceptibilities of powder Ni(OH)$_2$ and $\beta$-Co(OH)$_2$ were measured from $1.2^\circ$K to room temperature and the measurements of susceptibilities parallel and perpendicular to the c-axis were carried out on oriented Ni(OH)$_2$ sample and the determination of the spin axis was attempted.

The magnetizations of these hydroxides were measured up to 90 KOe at $4.2^\circ$K to determine whether they are metamagnetic or not.

II. EXPERIMENTALS

1) Preparation of Ni(OH)$_2$ sample

The particles of Ni(OH)$_2$ obtained by adding alkaline solution to nickelous salt solution are very fine (about 100 Å in size). It was inferred that these fine particles would show magnetically the characteristic behaviors such as superparamagnetism and superantiferromagnetism. In order to avoid these size effects, it is necessary that the particle size is larger than about 1 μ.

The sample for the magnetic measurements was prepared as follows; 0.1M-Ni(NO$_3$)$_2$·6H$_2$O aqueous solution was mixed with 0.2M-NH$_2$OH aqueous
solution and kept stirring at room temperature for 3 hours. The particles of Ni(OH)$_2$ were grown by hydrothermal reaction at 250°K for 7 hours.

This sample was confirmed to be Ni(OH)$_2$ by X-ray diffraction. Each particle of Ni(OH)$_2$ had a thin hexagonal plate-like shape and was 1~3μ in size as shown in the electron micrograph (Fig. 1 (a)).

2) Preparation of oriented sample of Ni(OH)$_2$

As shown in Fig. 1 (a), each particle of Ni(OH)$_2$ is thin hexagonal plate-like in shape. Therefore, the particles were preferentially oriented to one direction of the c-axis by sedimentation of particles in water.

When X-ray beams are reflected from the plane parallel to the c-plane of an ideally oriented sample, all (hkl) reflections except (001) reflections disappear from X-ray diagram. The X-ray diffraction diagram of oriented Ni(OH)$_2$ particles is shown in Fig. 2. From this diagram each particle was confirmed to be fairly oriented.

3) Preparation of β-Co(OH)$_2$ sample

It was reported by Milligan$^9$ that there are two modifications, α- and β-form in Co(OH)$_2$. When aqueous solution containing Co$^{2+}$ was mixed with alkaline aqueous solution, α-Co(OH)$_2$, which was blue amorphous precipitates, was obtained first but gradually disappeared and β-Co(OH)$_2$ of pink coloured crystalline was precipitated.

The sample for the magnetic measurements was prepared as follows; 0.1M-CoCl$_2$·7H$_2$O aqueous solution was mixed with 0.2M-NaOH aqueous solution at 20°C in the atmosphere of nitrogen gas to prevent Co$^{2+}$ from oxidation and the mixed solution was reacted for 24 hours. The pink coloured precipitates were confirmed to be β-Co(OH)$_2$ by X-ray diffraction and the average particle size was observed to be several microns as shown in Fig. 1 (b).

4) The magnetic measurements

The magnetic susceptibility was measured by AC Hartshorn bridge method
The Magnetic Properties of Ni(OH)$_2$ and $\beta$-Co(OH)$_2$

at temperatures from 1.2°K to 90°K and by a magnetic torsion balance from 90°K to room temperature. The temperature from 90°K to room temperature was determined by employment of Au-Co: Cu thermocouple and below 90°K it was determined by measuring the electric resistance of the calibrated Ge resistor.

For the measurements of the magnetization in the magnetic field 90 KOe, two inversely wound search coils with the same coil constants were placed in a magnetizing solenoid. A flux change in search coils due to the displacement of the specimen from one search coil to another was measured by recording flux meter. The temperature was determined by He vapor pressure.

III. RESULTS AND DISCUSSIONS

1) Ni(OH)$_2$

The temperature dependence of $\chi$ and $\chi^{-1}$ of random oriented powder sample is shown in Fig. 3.

The experimental fact that $\chi$ showed a very sharp maximum at 30°K, allows to suppose that the sample is antiferromagnetic below 30°K($T_N$). Susceptibilities parallel and perpendicular to the c-axis of oriented sample were measured to determine the spin axis in the antiferromagnetic state. As shown in Fig. 4, $\chi_\perp$, where $\perp$ means to be perpendicular to the c-axis of the oriented Ni(OH)$_2$ sample, had a value of $6.66 \times 10^{-2}$ emu/mol which was almost independent of the temperature below $T_N$. On the other hand, $\chi_\parallel$ parallel to the c-axis decreased with decreasing temperature through a prominent maximum value $10.11 \times 10^{-2}$ emu/
Hiroki Miyamoto

These results show the spin axis of Ni(OH)₃ to be parallel to the c-axis.

As shown in Fig. 3, χ in temperature range from about 150°K to room temperature obeyed Curie-Weiss law with a positive value of Tₜ (35°K). Effective Bohr magneton number was 3.2 μₜ, calculated from the equation of \( C = N \mu^2 \text{Beff}/3k \). Because of the positive sign of Tₜ, it was expected that the ferromagnetic internal field of Ni(OH)₃ was larger than the antiferromagnetic internal field and Ni(OH)₃ would be a metamagnetic substance.

The magnetization measurements were carried out up to 90 KOe at 4.2°K on the powder sample and the oriented sample, to study whether Ni(OH)₃ shows the metamagnetic property. As shown in Fig. 5, the abrupt increase of \( M_p \), magnetization of powder sample, was observed in about 55 KOe. The magnetization parallel to the c-axis of the oriented sample, \( M_\parallel \), increased more abruptly than \( M_p \) in 55 KOe and showed almost all the fraction of saturation magnetization at 90 KOe. Therefore the abrupt increase of \( M_p \) and \( M_\parallel \) observed in about 55 KOe shows to be due to the transition from antiferromagnet to ferromagnet. From these results, it is apparent that Ni(OH)₃ is concluded to be a metamagnetic substance and that the anisotropy field \( H_A \) is much stronger than the antiferromagnetic internal field \( H_E \). The magnetization perpendicular to the c-axis, \( M_\perp \),

![Fig. 3. Temperature dependence of susceptibility of powder Ni(OH)₃.](image-url)
increased almost linearly up to 90 KOe with the increasing field. By extrapolation of the magnetization, \( M_\perp \) was expected to be saturated with about 150 KOe.

According to the molecular field theory, \( M_\perp \) is saturated by the field which is twice as large as the antiferromagnetic internal field. As the antiferromagnetic internal field is equal to 55 KOe, \( M_\perp \) is expected to be saturated by the field about 110 KOe. This difference between the expected value and the experimental one may be due to a large anisotropy concluded above.

2) \( \beta\text{-Co(OH)}_2 \)

The temperature dependence of \( \chi \) and \( \chi^{-1} \) of powder sample is shown in Fig. 6. The experimental fact \( \chi \) represented a very sharp maximum when the temperature was 12.3°K, indicates that the sample is antiferromagnetic below 12.3°K. In the temperature range from about 100°K to room temperature \( \chi \) was observed to obey the Curie-Weiss law with a positive \( T_C(20°K) \). The effective Bohr magneton number was deduced to be 5.2 \( \mu_B \).

In order to study the magnetic behavior under the high magnetic field below \( T_N(12.3°K) \), the magnetization was measured up to 80 KOe at 4.2°K. As shown in Fig. 7, the magnetization did not show such an abrupt increase as Ni(OH)_2 but increased gradually with increasing field and was almost saturated above fields of about 35 KOe. This critical field (35 KOe) is much smaller than those usually associated with the exchange coupling in an antiferromagnetic structure which has the transition temperature of 12.3°K.

The magnetization in the low field, 0~5 KOe, increased in proportion to the
field, in the field ranging from 5 KOe to 22 KOe, increased in rather larger rate than initial susceptibility and in higher field, from 22 KOe to 28 KOe, increased linearly with the field. This magnetization curve is essentially identical to that observed in CoCl₂, thereby suggesting $H_A$ is smaller than $H_E$.

Therefore, the direction of spin axis was inferred to be at random in the low field but in the field range from 22 KOe to 28 KOe, to be perpendicular to the field. In general $H_A$ is much large when the spin axis is parallel to the c-axis. The result that $H_A$ is smaller than $H_E$ suggests the spin axis lies in the c-plane.

IV. CONCLUSION

Powder samples of Ni(OH)₂ and $\beta$-Co(OH)₂ were prepared from aqueous solution and the magnetic properties were studied. In the case of Ni(OH)₂, the

![Diagram of magnetic field dependence of magnetization of Ni(OH)₂ at 4.2°K.](image)

$M_p$: Magnetization of powder Ni(OH)₂.

$M_\parallel$: Magnetization parallel to the c-axis of Ni(OH)₂.

$M_\perp$: Magnetization perpendicular to the c-axis of Ni(OH)₂.

Fig. 5. Magnetic field dependence of magnetization of Ni(OH)₂ at 4.2°K.
magnetic measurements were carried out on oriented samples.

Susceptibility of Ni(OH)₂ exhibited an antiferromagnetic temperature dependence with the sharp maximum at 30.0°K. Well above Tₙ, χ obeyed the Curie-Weiss law and paramagnetic Curie point Tₛ was a positive value, 35°K. Below Tₙ, χ⊥, perpendicular to the c-axis of oriented Ni(OH)₂, was almost constant thereby the spin axis was parallel to the c-axis.

The magnetization parallel to the spin axis of Ni(OH)₂ exhibited the abrupt increase in the field of 55 KOe at 4.2°K. This abrupt increase was due to the transition from antiferromagnet to ferromagnet and showed that Ni(OH)₂ was the metamagnetic substance, of which Hₐ was much larger than Hₑ. Therefore it can be concluded that the magnetic moments of Ni atoms within a layer form a ferromagnetic sheet while the moments in adjacent layers are coupled antiparallel.

β-Co(OH)₂ exhibited a sharp maximum in χ at 12.3°K. The temperature dependence of χ of β-Co(OH)₂ was typical one of antiferromagnet except the fact that Tₛ was the positive value of 20°K.

The magnetization of β-Co(OH)₂ was saturated by the field of about 35 KOe, although the sharp transition such as in the case of Ni(OH)₂ did not occur. The magnetization curve of β-Co(OH)₂ is essentially similar to that of CoCl₂ which
Fig. 7. Magnetization of \( \beta \)-Co(OH)\(_2\) at 4.2°K.

has the metamagnetic structure with much smaller \( H_A \) than \( H_E \). Therefore the magnetic structure of \( \beta \)-Co(OH)\(_2\) was inferred to have analogous magnetic properties of Ni(OH)\(_2\) except that the magnetic easy axis lies in the c-plane.

ACKNOWLEDGEMENTS

The author is greatly indebted to Prof. T. Takada for valuable discussion and advices throughout the course of this work.

The author wishes to express his thanks to Dr. Y. Bando for warmful discussion and constant encouragement, and to Mr. M. Kiyama for his advices of sample preparation.

He also would like to express his sincere thanks to Prof. E. Kanda, Tohoku University, for valuable advices in the low temperature measurements. Thanks are due to Mr. T. Sato, Kanda Laboratory, for his help of susceptibility measurements.
