Bacterial cellulose (BC), cellulose produced by bacteria, consists of weblike networks of ribbon-shaped nanofibers of $10 \times 50 \text{ nm}^2$ in cross section.\textsuperscript{1-3} Since the cross-section size is at the nanoscale, BC could reinforce transparent plastics with less than 10% loss of light transmittance, even at fiber contents as high as 70 wt %.\textsuperscript{4} Furthermore, the high transparency was demonstrated for several different resins with widely different refractive indices.\textsuperscript{5} The transparency was also insensitive to temperature changes, which is very important in optoelectronics applications.\textsuperscript{3}

The nanofibers consist of bundles of semicrystalline extended cellulose chains, and therefore Young’s modulus and tensile strength are as high as those of aramid fibers.\textsuperscript{6-8} Surprisingly, the coefficient of thermal expansion (CTE) in the axial direction is very low, as low as that of quartz.\textsuperscript{9} Hence, this BC nanocomposite showed very low thermal expansion, similar to that of glass. Mechanical strength was five times higher than that of engineering plastics, while maintaining the ductility.\textsuperscript{4} Furthermore, drastic reduction in thermal expansion was also observed at low BC contents, due to the nanofiber network.\textsuperscript{10} Thus, the concept of BC-reinforced polymer composites are expected to lead the way to a wider use of many different optically transparent polymers, in applications where high transparency as well as low thermal expansion are important.

However, when we look at future applications of BC nanocomposites in optoelectronic devices, the hygroscopicity of cellulose causing dimensional instability of the composites seems to be a big drawback. In this context, we studied acetylation of BC, where the hydroxyl groups of cellulose are replaced by less hydrophilic acetyl groups.\textsuperscript{11,12} The acetylation significantly reduced the hygroscopicity of BC nanocomposites, while maintaining optical transparency and thermal stability.

BC pellicles with a thickness of 10 nm consisting of 1 vol% BC nanofibers and 99 vol% water were used as the starting material.\textsuperscript{5} The pellicles were pressed at 2 MPa and 20 °C for 2 min to remove the most of bulk water. Compressed BC pellicles were heated in 500 ml of acetic anhydride at 120 °C for 21 h. Acetylated BC pellicles were washed under running tap water for 2 days and then pressed at 2 MPa and 120 °C for 4 min to completely remove water. The acetylated BC sheets thus obtained were $30 \times 40 \text{ mm}^2$ and $45 \pm 5 \mu m$ thick with a density of 1.2–1.3 g/cm$^3$.

Based on scanning electron microscopy (SEM) images, the width of the nanofibers was found not to change after acetylation and the network structure was preserved (Fig. 1). Furthermore, X-ray analyses indicated that the crystallinity of BC did not change due to the acetylation, although the degree of substitution of acetylated BC sheets determined by elemental analysis was 0.17.

From the SEM images, it was also observed that the acetylated BC nanofibers are separated from each other in the sheet [Fig. 1(b)]. In contrast to this, the untreated BC nanofibers are so densely packed that the interstitial cavities are imperceptible [Fig. 1(a)]. The replacement of the surface hydroxyl groups by acetyl groups may interfere with mutual bonding of BC nanofibers to each other during the hot pressing to obtain dry sheets.

The BC sheets were impregnated with neat acrylic resins [type tricyclodecane dimethanol dimethacrylate (TCDDMA) with a refractive index of 1.532 and ABPE300 with a refractive index of 1.570, Mitsubishi Chemical Corp.] under reduced pressure and cured by UV light.

The BC nanocomposite with 60 wt% nanofibers reached a moisture content (MC) of 3.12% at 20°C and 55% relative humidity whereas the neat acryl resin TCDDMA reached a
MC of only 0.35% under the same conditions. When the fiber content of BC nanocomposites decreased from 60 to 35 wt %, their moisture content decreased from 3.12% to 1.49%. Interestingly, the acetylated BC nanocomposites adsorbed only 1.33% MC although the fiber content was as high as 66 wt %. This shows that 0.17° of substitution by acetyl groups produces a significant reduction in the hygroscopicity of BC nanofibers. As a consequence, when the fiber content was reduced to 33 wt % in combination with acetylation, a moisture content of only 0.80% was obtained. This is similar to that of the neat acrylic resin of TCDDMA.

The regular light transmittances of the acetylated BC nanocomposites were evaluated using a UV-visible spectrometer (U-4100, Hitachi High-Tech. Corp.). The acetylated BC nanocomposites exhibited high optical transparency, as shown in Fig. 2. Furthermore, when the spectra are compared carefully, the transparency of BC nanocomposites impregnated with TCDDMA (refractive index: 1.532) improved due to the acetylation [Fig. 2(a)]. For example, at the wavelength of 400 nm, the regular transmittance of untreated BC nanocomposite was 72.4%, while that of acetylated BC nanocomposite was 76.6%. In contrast, when an acrylic resin ABPE300 having a refractive index of 1.570 was impregnated, the regular transmittance of untreated BC nanocomposite deteriorated with acetylation, especially at shorter wavelengths [Fig. 2(b)]. In a previous study, we reported that the highest transparency of BC nanocomposites was attained at the refractive index of 1.570 (ABPE300), corresponding to the average refractive index of cellulose fiber. Considering that the refractive index of cellulose acetate decreases with the increase of the degree of substitution, the refractive index of BC would change due to acetylation. As a consequence, the optimum matrix refractive index for high transparency may shift.

The CTEs at 20–150 °C were evaluated using a thermal-mechanical analyzer (TMA/SS6100, SII Nanotechnology, Inc.). Interestingly the acetylation resulted in extremely low CTE of BC sheet (0.8 ppm/K), as compared to the CTE of untreated BC sheet (3 ppm/K). These results suggest that the acetylated BC nanofibers would enable further reduction of CTE in the nanocomposites. The addition of 66 wt % of acetylated BC nanofibers reduced the CTE of acrylic resin from 86 to 8 ppm/K. However, the untreated BC nanocomposite at a fiber content of 60 wt % also exhibited a similar CTE of 8 ppm/K. We found that Young’s modulus of BC sheets was reduced from 23.1 to 17.3 GPa due to the acetylation. This is probably because the acetylated BC nanofibers have fewer fiber-fiber interactions due to a decreased number of hydrogen bonds. Although sheets based on acetylated BC nanofibers have very low CTE, the reduced number of fiber-fiber interactions reduces the capability of the nanofiber network to restrain thermal expansion of a polymer matrix. This implies that if the number of fiber-fiber interactions is increased in acetylated BC sheets, the CTE of the resulting nanocomposites would be reduced.

Acetylation has been reported to improve the thermal degradation resistance of cellulose fibers, such as jute and sisal. The effects of acetylation on the thermal degradation of optical transparency were evaluated at 200 °C for different heating times. When the samples were subjected to
200 °C in air for 3 h, the optical transparency of untreated and acetylated BC nanocomposites was reduced as reported in Fig. 3. The acrylic resin sheet maintained its transparency. However, the reduction in transparency of acetylated BC nanocomposites was much smaller than for the untreated BC nanocomposites (Fig. 3). At the wavelength of 400 nm, the regular transmittance of untreated BC nanocomposite was decreased to 48.9% after heating for 1 h at 200 °C [Fig. 3(a)]. On the other hand, the regular transmittance of acetylated BC nanocomposite was 56.0% even after heating for 3 h at 200 °C [Fig. 3(b)]. Acetylation proved to be effective for improving the thermal degradation resistance of BC nanocomposites, which is a prerequisite to a wider use of BC nanocomposites in optoelectronic devices.

In conclusion, we fabricated nanocomposites reinforced with acetylated BC nanofibers. The acetylated BC nanocomposites showed reduced moisture adsorption and improved thermal degradation resistance regarding transparency. Furthermore, because the acetylated BC nanofibers attained extremely low CTEs, the acetylated BC nanofibers have the potential to enable a further reduction of CTE in the nanocomposites. Thus, the acetylation of bionanofibers is a promising modification for property enhancement of optically transparent materials, which require high transparency and low thermal expansion.

BC pellicles were a kind gift from Y. Kuwana (Fujicco Co., Ltd.). The authors would like to thank A. N. Nakagaito, RISH, Kyoto University for helpful discussion. They would also like to thank L. Berglund, Biofibre Materials Centre, Royal Institute of Technology for valuable revision of this letter. This work was supported by a grant-in-aid from the International Innovation Center, Kyoto University.
