Abstract.

Chorus emissions are triggered from the linear cyclotron instability driven by the temperature anisotropy of energetic electrons (10 - 100 keV) in the magnetosphere. Chorus emissions grow as an absolute non-linear instability near the magnetic equator due to the presence of an electromagnetic electron hole in velocity space. The transition process from the linear wave growth at a constant frequency to the nonlinear wave growth with a rising tone frequency is due to formation of a resonant current $-J_B$ anti-parallel to the wave magnetic field. The rising-tone frequency introduces a phase shift to the electron hole at the equator, and results in a resonant current component anti-parallel to the wave electric field $-J_E$, which causes the nonlinear wave growth. To confirm this triggering mechanism, we perform Vlasov Hybrid Simulations with J_B and without J_B . The run without J_B does not reproduce chorus emissions, while the run with J_B does successfully reproduce chorus emissions. The nonlinear frequency shift ω_1 due to J_B plays a critical role in the triggering process. The nonlinear transition time T_N for the frequency shift is found to be of the same order as the nonlinear trapping period, which is confirmed by simulations and observation. The established frequency sweep rate is ω_1/T_N , which gives an optimum wave amplitude of chorus emissions.

1. Introduction

Coherent electromagnetic waves called chorus emissions have frequently been observed in the inner magnetosphere [e.g., *Tsurutani and Smith*, 1974; *Santolik et al.*, 2003; *Santolik*, 2008; *Kasahara et al.*, 2009]. Chorus emissions typically consist of a series of rising tones generated near the magnetic equator, excited by energetic electrons from several keV to tens of keV injected into the inner magnetosphere at the time of a geomagnetic disturbance. In recent years chorus emissions have been studied extensively because of their role as a viable mechanism for accelerating radiation belt electrons as well as precipitating them into the polar atmosphere [*Summers et al.*, 1998; *Summers et al.*, 2002; *Miyoshi et al.*, 2003; *Horne et al.*, 2005; *Omura and Summers*, 2006; *Omura et al.*, 2007; *Katoh and Omura*, 2007; *Furuya et al.*, 2008; *Katoh et al.*, 2008; *Hikishima et al.*, 2010]. As a generation mechanism for chorus emissions, a backward wave oscillator (BWO) theory has been proposed by *Trakhtengerts* [1999]. The BWO theory assumes a step in the velocity distribution function, which has not been observed. Furthermore such a step can only influence the 'triggering phase' and can have no effect upon the plasma dynamics of the established chorus element with sweeping frequency as the resonance velocity will no longer match the location of the step in parallel velocity.

Numerical modeling of chorus emissions have been performed using a Vlasov-Hybrid Simulation (VHS) code based on narrow band field equations derived from Maxwell's equations and the linear equation of motion of cold plasma, under the assumption of a band-limited coherent whistler-mode wave [*Nunn*, 1990, 1993; *Nunn et al.*, 1997, 2009]. The initial wave amplitude and the wave phase are specified in such simulations. In

contrast to the VHS code, chorus emissions with rising tones were reproduced successfully starting from thermal noise in an electromagnetic electron-hybrid code, in which Maxwell's equations are solved directly together with the electron fluid equation for the cold dense electrons and the equations of motion for the hot resonant electrons [Kato and Omura, 2006; 2007]. The mechanism of the rising chorus emissions has been analyzed theoretically in terms of nonlinear wave growth due to the formation of an electromagnetic electron hole in the velocity phase space [Omura et al., 2008, 2009]. The relation between the wave amplitude and the frequency sweep rate in the generation region of chorus emissions has been derived [Omura et al., 2008, Equation (50)]. The validity of this relation has been demonstrated in a full-particle electromagnetic simulation [Hikishima et al., 2009] as well as in the electron-hybrid simulation [Kato and Omura, in press]. These simulations show that seeds of chorus emissions with rising tones are formed in a localized region near the magnetic equator. The seeds of emissions grow as a result of the formation of resonant current arising from nonlinear trajectories of resonant untrapped electrons.

Falling tone chorus emissions have also been observed by Cluster spacecraft, and modeled by Nunn et al. [2009]. In the present analysis, however, we focus our attention on rising tone chorus emissions, which has been studied more extensively by simulations [Kato and Omura, 2007; Hikishima et al., 2009; Nunn et al., 2009] as well as observations [Macusova et al., 2010; Cully et al., 2011].

The nonlinear wave growth theory [Omura et al., 2008, 2009] assumed a frequency sweep rate $\partial\omega/\partial t$ that drives the wave growth through the formation of a resonant current J_E parallel to the wave electric field. However, the mechanism for the formation of finite $\partial\omega/\partial t$ has not been clarified yet. Noting that the resonant current J_B parallel to the

wave magnetic field was included in previous studies based on the VHS code [Nunn *et al.*,
 1997, 2009], we have conducted an experiment to run the VHS code with and without J_B to
 find out the contribution of J_B to the generation of chorus emissions. As shown in Figure
 1, the run without J_B does not reproduce a rising tone chorus element, but a constant
 frequency emission, while the run with J_B does. Considering the contribution of resonant
 electrons, we first analyze the optimum condition for triggering chorus theoretically in
 section 2. We confirm the theoretical model by analyzing the result of the Vlasov Hybrid
 Simulation in section 3. In section 4 we present a summary and discussion.

2. Condition for triggering chorus emissions

We assume a whistler-mode wave propagating parallel to the static magnetic field $\mathbf{B}_0$
 with a wavenumber k and a constant frequency ω_0 satisfying the linear dispersion relation

$$c^2 k^2 - \omega_0^2 - \frac{\omega_0 \omega_{pe}^2}{\Omega_e - \omega_0} = 0 \quad . \quad (1)$$

where c , Ω_e , and ω_{pe} are the speed of light, the electron cyclotron frequency, and the
 electron plasma frequency, respectively. It is noted that the wavenumber k is a function
 of a distance h taken along the magnetic field line from the magnetic equator. The wave
 fields are in the transverse plane containing x - and y -axes. We then assume energetic
 electrons interacting with the wave satisfying the cyclotron resonance condition

$$\omega_0 - kv_{\parallel} = \frac{\Omega_e}{\gamma} \quad , \quad (2)$$

where γ is the Lorentz factor given by $\gamma = [1 - (v_{\parallel}^2 + v_{\perp}^2)/c^2]^{-1/2}$, and $v_{\parallel}$ and $v_{\perp}$ are
 electron velocities parallel and perpendicular to $\mathbf{B}_0$. Solving for $v_{\parallel}$, we can obtain an

explicit expression of the cyclotron resonance velocity

$$\tilde{V}_R = \frac{\tilde{\omega}^2 - \sqrt{\tilde{\omega}^4 + (\tilde{\omega}^2 + \tilde{V}_p^2)(1 - \tilde{\omega}^2 - \tilde{V}_{\perp 0}^2)}}{\tilde{\omega}^2 + \tilde{V}_p^2} \tilde{V}_p, \quad (3)$$

where $\tilde{\omega} = \omega_0/\Omega_e$, $\tilde{V}_R = V_R/c$, $\tilde{V}_p = V_p/c$, and $\tilde{V}_{\perp 0} = V_{\perp 0}/c$. The phase velocity is given by

$$V_p = \frac{\omega_0}{k} = c\delta\xi, \quad (4)$$

where $\xi^2 = \omega_0(\Omega_e - \omega_0)/\omega_{pe}^2$ and $\delta^2 = (1 + \xi^2)^{-1}$ [Omura *et al.*, 2008]. When we evaluate γ in the equations derived below, we substitute $v_{\parallel} = V_R$ and $v_{\perp} = V_{\perp 0}$, where $V_{\perp 0}$ is the average perpendicular velocity.

The electrons are organized in phase in the transverse plane, and form a resonant current that can trigger formation of a new wave field with a variable frequency ω , as demonstrated by a full-particle simulation by Hikishima *et al.* [2010].

We express the electric and magnetic field vectors of the total wave field in the transverse plane by the complex forms $\tilde{E}_w = E_w \exp(i\psi_E)$ and $\tilde{B}_w = B_w \exp(i\psi_B)$, respectively. From Maxwell's equations we obtain the following equations for the amplitude B_w of the wave magnetic field in the form [Omura *et al.*, 2008],

$$\frac{\partial B_w}{\partial t} + V_g \frac{\partial B_w}{\partial h} = -\frac{\mu_0 V_g}{2} J_E, \quad (5)$$

$$c^2 k^2 - \omega^2 - \frac{\omega \omega_{pe}^2}{\Omega_e - \omega} = \mu_0 c^2 k \frac{J_B}{B_w}, \quad (6)$$

where μ_0 is the magnetic permittivity in vacuum. The resonant current formed by resonant electrons is divided into two components J_E and J_B parallel to the transverse wave electric and magnetic fields, respectively. Details of the derivation of (5) and (6) are found in Appendix A of Omura *et al.* [2008].

While the resonant current J_E modifies the wave amplitude B_w , the quantity J_B/B_w changes the frequency ω of the triggered wave. It is noted that the wavenumber k or the wavelength does not change in space and time because it is imposed by the triggering wave with the constant frequency ω_0 in the present situation. Denoting the frequency deviation from ω_0 as ω_1 ($\omega = \omega_0 + \omega_1$) and assuming $\omega_1 \ll \omega_0$, we expand (6) around ω_0 to obtain

$$\left\{ 2\omega_0 + \frac{\Omega_e \omega_{pe}^2}{(\Omega_e - \omega_0)^2} \right\} \omega_1 = -\mu_0 c^2 k \frac{J_B}{B_w} , \quad (7)$$

where we made use of (1). Differentiating (1) with respect to ω_0 , we obtain

$$2c^2 k \frac{\partial k}{\partial \omega_0} = 2\omega_0 + \frac{\Omega_e \omega_{pe}^2}{(\Omega_e - \omega_0)^2} . \quad (8)$$

Using (8), we rewrite (7) as

$$\omega_1 = -\frac{\mu_0 V_g}{2} \frac{J_B}{B_w} . \quad (9)$$

where $V_g = \partial \omega_0 / \partial k$.

We consider the optimum condition for the nonlinear wave growth to take place, assuming that the electron hole is progressively formed in the velocity phase space within the time window defined by the nonlinear transit time T_N . Dynamics of a resonant electron is described by a set of simplified differential equations. Introducing the variables $\theta = k(v_{\parallel} - V_R)$ and the phase angle ζ between the perpendicular velocity $\mathbf{v}_{\perp}$ and the wave magnetic field $\mathbf{B}_w$,

$$\frac{d\zeta}{dt} = \theta , \quad (10)$$

and

$$\frac{d\theta}{dt} = \omega_{tr}^2 (\sin \zeta + S) , \quad (11)$$

where $\omega_{tr} = \omega_t \delta \gamma^{-1/2}$, and we have assumed that $v_{\parallel} \sim V_R$, i.e., $\theta \sim 0$. Here, ω_t is the trapping frequency given by $\omega_t = \sqrt{k v_{\perp} \Omega_w}$. The shape of the electron hole is determined by the inhomogeneity ratio given by

$$S = -\frac{1}{s_0 \omega \Omega_w} \left(s_1 \frac{\partial \omega}{\partial t} + c s_2 \frac{\partial \Omega_e}{\partial h} \right) , \quad (12)$$

where

$$s_0 = \frac{\delta V_{\perp 0}}{\xi c} , \quad (13)$$

$$s_1 = \gamma \left(1 - \frac{V_R}{V_g} \right)^2 , \quad (14)$$

and

$$s_2 = \frac{1}{2\xi\delta} \left\{ \frac{\gamma\omega_0}{\Omega_e} \left(\frac{V_{\perp 0}}{c} \right)^2 - \left[2 + \Lambda \frac{\delta^2 (\Omega_e - \gamma\omega_0)}{\Omega_e - \omega_0} \right] \frac{V_R V_p}{c^2} \right\} . \quad (15)$$

We have incorporated the variation of the cold electron density $N_e(h)$ along the magnetic field line as $N_e(h) = N_{e0} \Omega_e(h) / \Omega_{e0}$, where N_{e0} and Ω_{e0} are respectively the cold electron density and the electron gyrofrequency at the equator. We have $\Lambda = \omega_0 / \Omega_e$ for this inhomogeneous electron density model, while $\Lambda = 1$ for the constant electron density model [Omura *et al.* 2009].

The resonant currents J_E and J_B are expressed respectively as

$$J_E = -J_0 \int_{\zeta_1}^{\zeta_2} [\cos \zeta_1 - \cos \zeta + S(\zeta - \zeta_1)]^{1/2} \sin \zeta d\zeta , \quad (16)$$

and

$$J_B = J_0 \int_{\zeta_1}^{\zeta_2} [\cos \zeta_1 - \cos \zeta + S(\zeta - \zeta_1)]^{1/2} \cos \zeta d\zeta , \quad (17)$$

where $J_0 = (2e)^{3/2} (m_0 k \gamma)^{-1/2} V_{\perp 0}^{5/2} \delta Q G B_w^{1/2}$, and e and m_0 are the charge and rest mass of an electron. The factor Q represent the depth of the electron hole [Omura *et al.*, 2009].

The phase angles ζ_1 and ζ_2 define the boundary of the trapping wave potential as described by *Omura et al.* [2009]. The parameter G is the value of the velocity distribution function $g(v_{\parallel}, \zeta)$ in the trapping region around the resonance velocity.

We assume that the velocity distribution function f of hot energetic electrons is given in terms of the relativistic momentum per unit mass $u = \gamma v$; u has components $u_{\parallel} = \gamma v_{\parallel}$ and $u_{\perp} = \gamma v_{\perp}$, respectively parallel and perpendicular to the ambient magnetic field. We specify f as

$$f(u_{\parallel}, u_{\perp}) = \frac{N_h}{(2\pi)^{3/2} U_{t\parallel} U_{\perp 0}} \exp\left(-\frac{u_{\parallel}^2}{2U_{t\parallel}^2}\right) \Delta(u_{\perp} - U_{\perp 0}) \quad , \quad (18)$$

where $U_{\perp 0} = \gamma V_{\perp 0}$, $U_{t\parallel}$ is the thermal momentum in the parallel direction, and Δ is the Dirac delta function, and we have normalized f to the density of hot electrons N_h . Integrating over $u_{\perp}$ and taking an average over ζ , we obtain the magnitude G of the unperturbed distribution function $g(v_{\parallel}, \zeta)$ at the resonance velocity V_R as

$$G = \frac{N_h}{(2\pi)^{3/2} U_{t\parallel} U_{\perp 0}} \exp\left(-\frac{\gamma^2 V_R^2}{2U_{t\parallel}^2}\right) \quad . \quad (19)$$

Omura et al. [2008] found that the maximum value of $-J_E$ takes place when $S = -0.413$.

Solving (17) for $S = 0.413$, we obtain $J_B = -1.3J_0$, which is rewritten as

$$J_B = -1.3(2e)^{3/2} \left(\frac{B_w}{m_0 k \gamma}\right)^{1/2} V_{\perp 0}^{5/2} \delta Q G \quad . \quad (20)$$

The nonlinear transition time T_N for formation of the nonlinear resonant current is roughly estimated by the nonlinear trapping period T_{tr} given by

$$T_{tr} = \frac{2\pi}{\omega_{tr}} = \frac{2\pi}{\delta} \left(\frac{m_0 \gamma}{k V_{\perp 0} e B_w}\right)^{1/2} \quad , \quad (21)$$

where ω_{tr} is the trapping frequency [*Omura et al.*, 2008]. We define a ratio $\tau = T_N/T_{tr}$,

which is to be determined by numerical simulations in the next section.

198 Through the nonlinear transition time T_N , the electron hole is gradually formed. Along
 199 with formation of J_B , the frequency of the triggered wave gradually deviates from ω_0 to
 200 $\omega_0 + \omega_1$. From (9), (19), (20), and (21), we obtain the frequency sweep rate over the
 201 nonlinear trapping period as

$$\frac{\omega_1}{T_N} = \frac{1.3}{4} \pi^{-5/2} \frac{Q}{\tau} \left(\frac{\omega_{ph} V_{\perp 0} \delta}{\gamma c} \right)^2 \frac{V_g}{U_{t\parallel}} \exp \left(-\frac{\gamma^2 V_R^2}{2 U_{t\parallel}^2} \right) , \quad (22)$$

204 where ω_{ph} is the plasma frequency of the hot energetic electrons defined by $\omega_{ph}^2 =$
 205 $\mu_0 c^2 N_h e^2 / m_0$.

206 At the equator the inhomogeneity of the magnetic field is zero, and the second term on
 207 the right-hand side of (12) vanishes. Since the maximum nonlinear wave growth takes
 208 place when $S = -0.4$ [Omura *et al.*, 2008], we can derive from (12) the relation between
 209 the frequency sweep rate and the normalized wave amplitude at the equator $\Omega_w = e B_w / m_0$
 210 in the form,

$$\frac{\partial \omega}{\partial t} = \frac{0.4 s_0 \omega_0}{s_1} \Omega_w . \quad (23)$$

213 Equating the left-hand sides of (22) and (23), we obtain an optimum wave amplitude Ω_{wo}
 214 that can trigger the rising-tone chorus element as

$$\Omega_{wo} = \frac{s_1 \omega_1}{0.4 s_0 \omega_0 T_N} . \quad (24)$$

217 From (22) and (24), we obtain

$$\tilde{\Omega}_{wo} = 0.81 \pi^{-5/2} \frac{Q}{\tau} \frac{s_1 \tilde{V}_g}{s_0 \tilde{\omega} \tilde{U}_{t\parallel}} \left(\frac{\tilde{\omega}_{ph} \tilde{V}_{\perp 0} \delta}{\gamma} \right)^2 \exp \left(-\frac{\gamma^2 \tilde{V}_R^2}{2 \tilde{U}_{t\parallel}^2} \right) , \quad (25)$$

220 where $\tilde{\Omega}_{wo} = \Omega_{wo} / \Omega_{e0}$, $\tilde{\omega}_{ph} = \omega_{ph} / \Omega_{e0}$, and $\tilde{U}_{t\parallel} = U_{t\parallel} / c$.

Finally we can evaluate the nonlinear transition time using the wave amplitude obtained

above. Using (4), we rewrite (21) as

$$T_N \Omega_{e0} = 2\pi\tau \left(\frac{\gamma\xi}{\tilde{\omega}\tilde{V}_{\perp 0}\tilde{\Omega}_{w0}\delta} \right)^{1/2}, \quad (26)$$

The triggered chorus element should satisfy another condition to grow as a nonlinear absolute instability at the equator. The wave amplitude of the triggered emission should be greater than the threshold for the nonlinear wave growth [Omura *et al.*, 2009], which is given by

$$\tilde{\Omega}_{th} = \frac{100\pi^3\gamma^3\xi}{\tilde{\omega}\tilde{\omega}_{ph}^4\tilde{V}_{\perp 0}^5\delta^5} \left(\frac{\tilde{a}s_2\tilde{U}_{t\parallel}}{Q} \right)^2 \exp \left(\frac{\gamma^2\tilde{V}_R^2}{\tilde{U}_{t\parallel}^2} \right), \quad (27)$$

where $\tilde{a} = ac^2/\Omega_{e0}^2$, and a is a coefficient defining the parabolic variation of the magnetic field around the equator as $\Omega_e = \Omega_{e0}(1 + ah^2)$. The coefficient a is specified by the L value and the Earth's radius R_E as $a = 4.5/(LR_E)^2$.

3. Simulations of rising tone emissions

We performed simulations of rising tone emissions by the VHS code, in which the equations equivalent to (5) and (6) are solved numerically along with the Vlasov equation for the resonant electrons [Nunn *et al.*, 1990, 1993, 2009]. To find out the importance of the resonant current J_B in generating chorus emissions, we first performed a run in which both J_E and J_B are calculated and the wave field is updated by them. The run produced a rising tone emission as shown in Figure 1(a). We then performed the second run with $J_B = 0$. The second run did not reproduce the rising tone emission as shown in Figure 1(b). A constant frequency emission did result with symmetric upper and lower resonant sidebands. We now recognize the importance of the resonant current J_B as analyzed in the preceding section.

244 The parameters used in the VHS run are the following. The electron cyclotron frequency
 245 f_c is 8 kHz at the magnetic equator. The electron plasma frequency f_p is 18.8 kHz, which
 246 gives $\tilde{\omega}_p = 2.35$. Assuming $L = 4.79$, we have $\tilde{a} = 1.72 \times 10^{-7}$. The velocity distribution
 247 assumed in the VHS code is approximated by (18) with $V_{\perp 0} = 0.4584c$, $U_{t\parallel} = 0.2396c$, and
 248 $\tilde{\omega}_{ph} = 0.1664$ ($N_h/N_c = 0.005$). These parameter gives equatorial linear growth rate of
 249 600 dB/s, which is in rough agreement with path integrated gain of whistler-mode waves
 250 evaluated based on the THEMIS spacecraft observation [Li *et al.*, 2009].

251 Figures 2(a) and 2(b) show the spatial and temporal variation, in dimensionless units, of
 252 wave amplitude B_w/B_0 and wave frequency ω/Ω_{e0} , respectively. The incoming triggering
 253 pulse has an initial amplitude $B_{w0} = 4.2 \times 10^{-5}$ (12pT) and duration $8.4 \times 10^3 \Omega_{e0}^{-1}$ (167
 254 ms) and frequency $\omega/\Omega_{e0} = 0.4$ (3.2 kHz). Its amplification as it progresses to the equator
 255 is clearly visible in Figure 2a, at which point its amplitude is large enough for nonlinear
 256 trapping to occur and for triggering to take place. At about $t\Omega_{e0} \sim 9000$ a riser generation
 257 region is firmly established with a wave generation point at the equator and a profile
 258 leading edge some $100 \sim 500$ units upstream from the equator.

259 From the temporal and spatial variation of local frequency in Figure 2(b) we see an
 260 initial drop in frequency due to nonlinear trapping in the incoming pulse when it is in the
 261 positive inhomogeneity region upstream from the equator $S > 0$. The region of much lower
 262 frequencies near $t\Omega_{e0} \sim 8000$ is not significant as it corresponds to very small amplitudes
 263 in the wake of the incoming pulse. After $t\Omega_{e0} \sim 9000$ we see a rising frequency in the
 264 equatorial region, and after $t\Omega_{e0} \sim 11000$ the progressive establishment of a frequency
 265 gradient across the interaction region.

266 By plotting the distribution function of resonant electrons in the $(v_{\parallel} - \zeta)$ phase space,
 267 we find that the depletion of the electrons in the trap at the resonance velocity is about 22
 268 percent of the surrounding energetic electrons. Assuming $Q = 0.25$ with the parameters
 269 of the VHS run, we calculated the optimum wave amplitudes given by (25) in solid lines
 270 in Figure 3(a). The numbers attached to the lines are the time scale factors τ . We also
 271 plot the threshold for the nonlinear wave growth given by (27) in a dashed line. Figure
 272 3(b) shows the nonlinear time scale T_N given by (26) for different values of τ .

273 In Figure 4 we plot simultaneous time histories at the equator ($h = 0$) of wave amplitude
 274 and frequency as well as resonant particle current components J_E and J_B in arbitrary
 275 units. Figure 4(a) shows wave amplitude progression. Significant amplitudes $\sim 2 \times 10^{-4}$
 276 are established after $t\Omega_{e0} = 5000$, but there is a drop out around $t\Omega_{e0} \sim 9000$ when
 277 the wave profile slips downstream from the equator. Figure 4(b) shows the progression
 278 of equatorial frequency. After an initial drop a positive frequency gradient is abruptly
 279 established at $t\Omega_{e0} \sim 9000$ of magnitude $1 \times 10^{-5}\Omega_{e0}^2$ (4 kHz/s). From (23), we can
 280 estimate the average wave amplitude $B_w/B_{oEQ} = 1.3 \times 10^{-4}$ (37 pT) that results in the
 281 frequency sweep rate. Assuming this amplitude is the optimum amplitude given by (25),
 282 we find $\tau = 1.0$. Substituting this value of τ into (26), we find $T_N\Omega_{e0} = 640$ (13 ms).

283 Figure 4(e) shows the time development of the nonlinear frequency shift term ω_1 . The
 284 latter is quite interesting. At around $t\Omega_{e0} \sim 9500$ it rises quite quickly to a value ~ 0.006
 285 (50 Hz) which is then sustained. The development time is nearly equal to T_N obtained
 286 above. We can also confirm that the quotient ω_1/T_N agrees with the frequency sweep rate
 287 $\partial\omega/\partial t = 1 \times 10^{-5}\Omega_{e0}^2$ in accordance with the assumption of the optimum wave amplitude.

288 As a result of trapping in the negative inhomogeneity region $h > 0$, we get an electron
 289 hole and a significant build up of a large nonlinear current J_B at the equator as shown
 290 in Figure 4(c). This is as expected since the inhomogeneity S at $h = 0$ is initially zero
 291 giving a phase trapping angle anti parallel to the wave magnetic field (phase of 180 degrees
 292 relative to B_w). We find formation of a negative J_B around $t\Omega_{e0} = 6500 \sim 8500$, but the
 293 wave amplitude is much larger than the optimum wave amplitude, and the nonlinear
 294 frequency shift was too small to trigger the rising tone. As the positive frequency sweep
 295 rate becomes established at later time as shown in Figure 4(b), S shifts to a value ~ -0.4
 296 which enables us to easily interpret the J_E profile in Figure 4(d). The current J_E is
 297 initially close to zero as expected for $S = 0$, but acquires a significant negative component,
 298 from about $t\Omega_{e0} \sim 9500$ giving nonlinear growth, as the trapping angle rotates to a phase
 299 of approximately 166 degrees.

300 We performed a few other runs of rising chorus elements by the VHS code with different
 301 parameters, and found the same sequence of the initial formation of the negative J_B
 302 followed by gradual formation of the negative J_E along with establishment of the finite
 303 frequency sweep rate. We also found $\tau \sim 1.0$.

304 In Figure 5(a) we plot the optimum wave amplitude and the threshold for the nonlinear
 305 wave growth with parameters used in an electron hybrid simulation [Kato and Omura
 306 [2007]: Omura *et al.*, 2008] $\tilde{a} = 9.8 \times 10^{-7}$, $\tilde{V}_{\perp 0} = 0.6$, $\tilde{U}_{t\parallel} = 0.3$, $\tilde{\omega}_{pe} = 4$, and $\tilde{\omega}_{ph} = 0.113$.
 307 We assume $Q = 0.5$ and different values of $\tau = 0.25, 0.5, 1.0, 2.0$. Noting that the simulated
 308 chorus emissions have frequency spectra starting from $\omega = 0.2\Omega_{e0}$ with the wave amplitude
 309 $B_w \sim 4 \times 10^{-4} B_{0EQ}$ at the equator (Figures 4 and 5 of Omura *et al.* [2008]), we find that
 310 the optimum amplitude with $\tau = 0.25 \sim 0.5$ agrees with the simulation result, because

the frequency range above $\omega = 0.2$ satisfies the necessary condition for the nonlinear wave growth $\tilde{\Omega}_{wo} > \tilde{\Omega}_{th}$.

In Figure 5(b), we plot the optimum wave amplitude and the threshold with parameters used in a full-particle simulation by *Hikishima et al.*[2009]: $\tilde{a} = 5.1 \times 10^{-6}$, $\tilde{V}_{\perp 0} = 0.29$, $\tilde{U}_{t\parallel} = 0.2$, $\tilde{\omega}_{pe} = 5$, and $\tilde{\omega}_{ph} = 0.40$. In both cases, we assume $Q = 0.5$ and different values of $\tau = 0.25, 0.5, 1.0, 2.0$. Figure 8 of *Hikishima et al.* [2009] shows chorus emissions starting from $\omega = 0.16\Omega_{e0}$ with a wave amplitude $B_w \sim 1 \times 10^{-3}B_{0EQ}$ at the equator. We find good agreement between the optimum amplitude with $\tau = 0.5$ and the frequency spectra of the simulation result.

It is also interesting to note that the frequency range that satisfies $\tilde{\Omega}_{wo} > \tilde{\Omega}_{th}$, shown in Figure 5(a), agrees with the width of the wave spectra found in the simulation result. A chorus element undergoes a strong wave amplitude modulation through its evolution in frequency. Even if the nonlinear wave growth is terminated because of the amplitude modulation, a new triggering process can take place when the optimum condition of the wave amplitude is satisfied, and the rising tone is resumed. Therefore, while the optimum wave amplitude is larger than the threshold for the nonlinear wave growth, the frequency continues to increase, forming the chorus element.

4. Summary and Discussion

We have obtained an optimum wave amplitude that can trigger a rising tone chorus element. When the optimum wave amplitude given by (25) is reached by the linear wave instability at a specific frequency driven by the temperature anisotropy of resonant electrons near the equator, a triggered emission arises with a rising frequency due to gradual formation of the negative J_B and with an increasing wave amplitude due to the

negative J_E induced by the positive frequency sweep rate. An electromagnetic electron hole is formed in the velocity phase space with $S \sim -0.4$. An absolute nonlinear instability takes place above the threshold given by (27).

For comparison with an observation by the Cluster spacecraft [*Santolik et al.*, 2003; *Santolik*, 2008], we plot the optimum wave amplitude and the threshold for the nonlinear wave growth in Figure 6(a), and the theoretical frequency sweep rate $\partial f/\partial t$ in Figure 6(b). Based on the observation at $L = 4.4$, which gives $\tilde{a} = 2 \times 10^{-7}$, we assumed parameters as $\omega_{pe}/\Omega_{e0} = 2.4$, $\tilde{V}_{\perp 0} = 0.3$, and $\tilde{U}_{t\parallel} = 0.2$. The energy of the resonant electrons are 50 keV for $\omega/\Omega_{e0} = 0.37$ (3 kHz). Since the parameters are very close to the VHS run, we use $Q = 0.25$ and varied the time scale parameter as $\tau = 0.25, 0.5, 1.0, 2.0$. The optimum wave amplitude and the frequency sweep rate varies depending on the density of energetic electrons N_h . From the observation, we can find the frequency sweep rates, which do not change much through propagation. On the other hand, the wave amplitude can change substantially through propagation from the source region to the observation point. Therefore, we can infer the physical parameters at the generation region from the frequency sweep rate of the observed chorus emissions. Chorus emissions reported by *Santolik et al.*[2003] consist of rising tone elements starting from $2 \sim 3$ kHz with the frequency sweep rate ~ 15 kHz/s. We find a good agreement with the case $N_h/N_c = 0.04$ and $\tau = 0.25 \sim 0.5$. The wave amplitude in the generation region is estimated as large as $100 \sim 300$ pT.

It is also interesting to note that the frequency sweep rate give by (22) does not depend on the wave amplitude of the triggering wave. The physical plasma parameters and the frequency of the triggering wave determine the frequency sweep rate. Then the effective

356 wave growth takes place with the wave amplitude of the triggered wave, which satisfies
357 the condition (23) at the magnetic equator.

358 Finally we can construct the following scenario of the chorus generation process, sum-
359 marizing the recent studies [Omura *et al.*, 2008, 2009] and the present analysis.

360 **1. Linear Phase:** Whistler-mode waves grow due to a linear instability driven by
361 temperature anisotropy of energetic electrons. A constant-frequency wave with the max-
362 imum linear growth rate becomes dominant to form a coherent wave phase. The linear
363 growth rate maximizes at the magnetic equator where the flux of energetic electrons at
364 the resonance velocity becomes largest. The seed of the triggering wave is the thermal
365 fluctuation at some distance from the equator. It propagates toward the equatorial region,
366 undergoing the convective linear growth to form a coherent wave near the equator.

367 **2. Nonlinear Phase 1:** As a result of the nonlinear dynamics of electrons at or near
368 the resonance velocity of the triggering coherent wave, a hole in the velocity distribution
369 function at the location of the resonant particle trap is formed. The negative resonant
370 current J_B is formed, resulting in the nonlinear frequency shift ω_1 taking place over T_N ,
371 which is of the same order as the nonlinear trapping time T_{tr} . The ratio T_N/T_{tr} ($= \tau$) is
372 $0.25 \sim 1.0$. The frequency sweep rate is the nonlinear frequency shift ω_1 divided by the
373 nonlinear transition time T_N .

374 **3. Nonlinear Phase 2:** Along with the establishment of the frequency sweep rate
375 ω_1/T_N , the nonlinear resonant current J_E is formed, resulting in the nonlinear wave
376 growth. Formation of the negative J_E results in the nonlinear wave growth as an absolute
377 instability at the magnetic equator. The nonlinear instability starts from an optimum
378 amplitude that is required to maximize J_E with the inhomogeneity ratio $S = -0.4$. The

initial evolution of the wave amplitude and frequency is described by the chorus equations

[*Omura et al.*, 2009].

4. Nonlinear Phase 3: A chorus element is formed at the magnetic equator, and propagates away from it. As the wave propagates away from the equator, the zero order field gradient increases as does the wave amplitude due to the nonlinear wave growth. While $-1 < S < 0$, trapping is allowed and the chorus element continues to grow as it propagates away from the equator.

In the linear phase, the triggering wave grows from the thermal fluctuation through the convective linear growth. Evaluation of the path-integrated gain of the linear instability was performed by *Li et al.* [2009]. It is noted, however, that the linear growth rate is applicable only to the triggering waves, and not to the chorus emissions, which are generated through the nonlinear processes as described above.

The initial appearance of J_B followed by J_E in the initial nonlinear growth phase of the triggered emissions is also observed in the HAARP HF ionospheric heating experiment [*Golkowski et al.*, 2010]. From the growth of the observed wave amplitudes and phases of HAARP-generated whistler-mode echoes, the magnitudes of the resonant currents are estimated. The analysis shows that the magnitude of J_B is greater than that of J_E , which is consistent with the VHS code result shown in Figure 4 and the theoretical model of an electromagnetic electron hole assumed in the nonlinear wave growth theory.

Gibby et al. [2008] tried to reproduce triggered emissions, using a more classical Vlasov method such as developed by *Denavit* [1972; 1985] and by *Besse and Sonnendrucker* [2003] in the semi Lagrangian method. These methods advance the distribution function by applying Liouville's theorem to one step particle trajectories, and then interpolating

distribution function back onto the phase space grid. These methods can have poor robustness to distribution function filamentation and give rise to an unphysical diffusion in distribution function due to the successive interpolation procedures. The VHS method suffers from neither of these problems. The code by *Gibby et al.* [2008] does not update wave phase properly when wave amplitude is very small and for a broadband simulation has a rather low resolution in phase space, which may be why the code does not trigger emissions. *Gibby et al.* [2008] presents interesting and plausible data, supported by his simulations, suggesting that in the key down case saturation may arise from marked spectral broadening which destroys particle trapping and thus nonlinear growth rates.

At the magnetic equator, the nonlinear wave growth saturates due to a subsequent nonlinear effect [*Hikishima et al.*, 2010]. The detailed analysis of the saturation mechanism is left as a future study.

Acknowledgments. Computation in the present study was performed with the KDK system of Research Institute for Sustainable Humanosphere (RISH) at Kyoto University. This work was supported by Grant-in-Aid 20340135 of the Ministry of Education, Science, Sports and Culture of Japan. D. Nunn thanks Kyoto University for Visiting Professorship at RISH.
