6

Possibility of Creating a Common Currency Basket for East Asia*

Eiji Ogawa and Kentaro Kawasaki

Introduction

After East Asian countries experienced the Asian currency crisis, it has been regarded that regional financial cooperation in East Asia is necessary among East Asian countries in order to prevent a currency crisis in the future. A regional financial cooperation has been realized in a form of the Chiang Mai Initiatives that is a network of currency swap arrangements among ASEAN + 3 (China, Japan, and Korea). The movements have given us momentum to activate policy dialogues in a field of international monetary arrangements among East Asian countries. This paper has an objective to consider a desirable regional currency arrangement in East Asia, which is expected to be an important topic in policy dialogue among East Asian countries in the future.

Our experience of the Asian currency crisis remind us of a fact that the de facto dollar peg was inadequate for East Asian countries that have close economic relationships with not only the United States but also Japan, European countries, and intra-regional countries. It follows that if a regional currency arrangement will be established in East Asia, regional currencies should have stable linkages with each other and should be stable in terms of not a single major currency but a currency basket. The EU created a single common currency, the euro, placing its base on the European Currency Unit (ECU), which had been used a currency unit in the EU before they introduced the euro into the EU. In the case of the ECU, member country currencies were linked with the ECU consisted of the member country currencies while the ECU was floating against the US dollar and the Japanese yen. A possible common currency in East Asia will be

We thank Yu Yongding for providing us Chinese data.

contrast to the ECU.

In addition, we investigate possibility of creating a common currency basket in East Asia according to the optimal currency area theory. Bayoumi, Eichengreen, and Mauro (2000) used a structural VAR model to make an empirical analysis on an optimal currency area in East Asia. We use a Generalized Purchasing Power Parity (G-PPP) model to analyze the issue. We investigate which parts of East Asian countries will be able to create a common currency area. We have analytical results that ASEAN5 countries and Korea will be able to form a common currency area and that a common currency basket will be more applicable as an anchor currency than the US dollar if these countries form a common currency area.

This paper consists of five sections. Next section places stress on creation of a common currency basket for East Asian countries in order to resolve a kind of coordination failure in exchange rate policies among East Asian countries. In section 3, we empirically analyze whether parts of East Asia will be able to become a common currency area with a currency basket as an anchor currency in order to consider possibility of creating a common currency basket in East Asia. We use a G-PPP model to investigate which of East Asian countries can create a common currency area with a currency basket as an anchor currency. In section 4, we report our empirical results. In section 5, we discuss about policy implication for a common currency area in East Asia from our empirical results. In conclusion, we summarize our consideration on possibility of creating a common currency basket for East Asia.

A common currency basket for East Asian countries

Some empirical researches found that a currency basket system would contribute to stabilizing trade balances and capital flows in East Asian countries. Ito, Ogawa, and Sasaki (1998) estimated optimal weights on the US dollar and the Japanese yen in a currency basket, which would have stabilized trade balances in East Asian countries before the Asian currency crisis. Results of the estimation showed that the optimal weights on the US dollar were smaller than their actual weights that were estimated by Frankel and Wei (1994) and Kawai and Akiyama (1998). It implies that it was not a *de facto* dollar peg system but a currency basket peg system that would have stabilized their trade balances.

Ogawa and Sun (2001) simulated capital inflows to three crisis-hit countries, which include Thailand, Indonesia, and Korea, under a currency basket peg system where

weights on the US dollar and the Japanese yen had been 50%: 50% in a currency basket. Results of the simulation concluded that the *de facto* dollar peg system stimulated capital inflows to the crisis-hit countries before the Asian currency crisis.

We should consider why the monetary authorities of East Asian countries tended to choose a *de facto* dollar peg system rather than a currency basket peg system. In fact, linkages of East Asian countries to the US dollar recently have returned to the high level before the crisis as McKinnon (2000) and Ogawa (2002a) pointed out. A reason why the monetary authorities are unwilling to adopt a currency basket peg system is related with a kind of coordination failure in choosing exchange rate system. The first mover to a currency basket peg system might temporarily destabilize its relations with the neighbor countries that are still pegged their home currencies to the US dollar as shown in a prisoners' dilemma in a game theory. [1]

Ogawa and Ito (2002) used a theoretical two-country model to examine an optimal exchange rate system for East Asian countries that export goods to the United States, Japan, and neighboring countries in order to minimize the fluctuation of trade balances in home countries, in the environment where the yen-dollar exchange rate fluctuates. It was shown how an East Asian country's choice of the exchange rate system (or weights in the basket) is dependent on the neighbor country's choice. The dollar weights in the currency baskets of the two countries are determined as Nash equilibrium. There may be multiple equilibriums, and a "coordination failure" may result.[2]

Under uncertainty about the future movements in the exchange rate of the US dollar vis-à-vis the Japanese yen, the monetary authorities have higher degree of possibility of facing with the coordination failure in choosing exchange rate system. Suppose that alone the monetary authorities of a country switch their exchange rate policy to the currency basket peg system while the other monetary authorities of the neighbor countries keep the dollar peg system. A currency of the country that adopted the currency basket peg system would appreciate against the currencies of the neighbor countries if the US dollar depreciated against the Japanese yen. Therefore, under such uncertainty, the monetary authorities tend to work out a "wait-and-see" strategy if they are averse to risk.

All of the monetary authorities are likely to take such a "wait-and-see" strategy if they are all risk averse. The situation is a so-called prisoner's dilemma in a game theory.

---

[1] Bénassy-Quéré (1999) and Ohno (1999) analyzed how the monetary authorities peg the home currency to the US dollar as a result of a coordination failure.

[2] Ogawa (2002b) and Nakata and Ogawa (2002) conducted empirical analyses on possibility of coordination failure in choosing exchange rate system in East Asia. They found the possibility of the coordination failure among the ASEAN, China, and Korea.

All of the monetary authorities cannot help but choose to keep the dollar peg system, which means Nash equilibrium, even though they should know that there is a better cooperative solution Coordination among some of the monetary authorities in East Asian countries is necessary for shifting the situation from the Nash equilibrium to a cooperative solution.

A form of coordination is international policy coordination for arrangements of international monetary system. For example, all of the monetary authorities of the countries in a regional area might agree on an arrangement that they create a common currency that consists of a currency basket. They might make references to the common currency in conducting their exchange rate policy. A rigid arrangement is that all of the monetary authorities in the regional area peg their home currencies to a common currency basket. On one hand, one of more flexible arrangements is that they target the home currencies in a wider band around a central exchange rate of the home currencies vis-à-vis a common currency basket.

In either case, it is necessary to create a common currency basket that the monetary authorities of the countries make reference to when they conduct their exchange rate policies. Such regional currency arrangements might help to prevent competitive devaluation among the related currencies in a region. If the monetary authorities of a country devalue its home currency, the devaluation worsens price competitiveness of products made in neighbor countries. For that reason, the monetary authorities of the other countries should have an incentive to devalue their home currency, following the first country's deflator. The regional currency arrangements that the monetary authorities in a region make a commitment to a coordinated exchange rate policy of making references to a common currency basket would prevent from a possible competitive devaluation.

Here we should consider possibility of introducing a common currency basket in East Asia. What is a condition where we can use a common currency basket among some countries? It is clear that optimal weights on currencies in a currency basket should be almost the same among the counties. Thus, an area where a common currency basket is used is related with a common currency area.

According to the optimal currency area theories, possibility of establishing a common currency area in a region depends on whether the region is an optimal currency area or not. It is pointed out in the optimal currency area theories that some factors determine an optimal currency area. Mundell (1961) regarded mobility of labor as a necessity of common currency area while McKinnon (1963) regarded openness of economy as another necessity. Moreover, symmetry of shocks was pointed out as a factor

for optimal currency area (Bayoumi and Eichengreen (1993)). It is possible to form an optimal currency area because it is unnecessary to make intra-regional adjustments in a region where symmetric shocks happen. Symmetry of supply shocks is focused on because supply shocks have long run effects on GDP while demand shocks have no long run effects on GDP in a situation where the natural unemployment hypothesis holds. The supply shocks mean ones that have effects on production function like productivity shocks and oil price shocks.

Bayoumi, Eichengreen, and Mauro (2000) made an empirical analysis on an optimal currency area in East Asian region[3]. Their results show that correlations are relatively higher among Malaysia, Indonesia, and Singapore. Also, a correlation is higher between Singapore and Thailand. Therefore, these ASEAN four countries might be able to form an optimal currency area. Moreover, supply shocks in Japan has a positive correlation with Taiwan, Korea, and Australia. On one hand, it has lower correlation with ASEAN countries except for Thailand.

An empirical analysis of optimal currency area for East Asia

We further extended earlier works of Kawasaki (2000) and Ogawa and Kawasaki (2001) in order to analyze empirically an optimum currency area for East Asia. In this paper, we also use a Generalized Purchasing Power Parity (G-PPP) model to conduct the empirical analysis as well as in earlier works. Now we use a common currency basket as well as the US dollar as an anchor currency. We defined the common currency basket as one that is composed of three major currencies: the US dollar, the Deutsche mark, and the Japanese yen. We supposed that each of the three currencies had same weights in the currency basket.

The G-PPP model is extended from a simple PPP model by taking into account difficulties in holding PPP because frequently occurred nominal and real shocks continuously have effects on macro fundamentals. Even in the long run, changes in a bilateral exchange rate depend not only on changes in relative prices between the related two countries but also on those in relative prices among the two countries and other countries. Price levels in other countries may have effects on domestic price levels in the two countries because prices of intermediate goods imported from abroad may have effects on prices of domestic products. Therefore, it is assumed in the G-PPP model that there are common factors among some bilateral real exchange rates of the home

[3] Sato, Zhang, and Mcaleer (2001) used a similar structural VAR method to investigate an optimal currency area for East Asia.

currency vis-à-vis currencies of foreign countries with which the home country has strong economic relationships. Thus, the real exchange rates have stable equilibrium in the long run if they have strong economic relationships with each other.

The G-PPP model explains that a PPP holds if a linear combination of some bilateral real exchange rate series has equilibrium in the long run, even though each of the bilateral rate series is nonstationary. Therefore, we investigate such stable linear combinations in the long run composed with some bilateral real exchange rate series based on the cointegration analysis of Johansen and Juserius (1990). Using this econometric method, we can find the optimal members in the common currency area.

(1) Data

Our sample period in the empirical tests for G-PPP model covers from October 1985 to June 1997. Our sample countries are seven East Asian countries which include Korea, Singapore, Malaysia, Thailand, the Philippines, Indonesia, and China. Real exchange rates were based on monthly data of nominal exchange rates and consumer price index of the related countries.[4] The rest of data are from IMF, *International Financial Statistics* (CD-ROM).

(2) Anchor currencies and common currency areas

We regarded either the US dollar or the common currency basket that was composed of the US dollar, the Deutsche mark, and the Japanese yen as an anchor currency. Since we supposed that each of three major currencies had same weights in the currency basket, the real exchange rate between each of the seven East Asian currencies and the currency basket could be defined as follows,

$$re_{i,CB} = \left(re_{i,US}\right)^{(1/3)} \cdot \left(re_{i,JP}\right)^{(1/3)} \cdot \left(re_{i,DM}\right)^{(1/3)}. \qquad (1)$$

We analyzed which of the seven East Asian countries (Korea, Singapore, Malaysia, Thailand the Philippines Indonesia, and China) can form a common currency area with either the currency basket or the US dollar as an anchor currency. In this paper, we focused on the cases in which more than two countries are included in the linear combinations, therefore, each combination consisted of three, four, five, six, or seven countries was examined as an optimal currency area. Then, we conducted "Johansen test" for 198 possible linear combinations. Since the G-PPP model is assumed that all

[4] Although Enders and Hurn (1994) used the wholesale price index to calculate the real exchange rate, we use the consumer price index because we assume two commodities which include the tradable and the non-tradable goods. See Kawasaki (2002) for details of the theoretical background.

real exchange rates in a common currency area must be nonstationary, we conducted the unit root tests: Augmented Dickey-Fuller (ADF) test, and Kwaiatkowski, Phillips, and Shmidt and Shin (KPSS) type unit root test, for each real exchange rate series, and confirmed all series have a unit root.

(3) Cointegration analysis

We used the Johansen method (Johansen and Juselius (1990)) to test whether a long run relationship can exist in the vector auto regressive model (VAR). In the case that there is a long run relationship in the VAR model, we can recognize that variables in the model are cointegrated, and that equilibrium errors from the long run relationship must be corrected in the long run. Assuming that variables in the model are cointegrated, we can rewrite the VAR model as the error correction model (ECM) as follows:

$$\Delta R_t = \sum_{l=1}^{k-1} \Gamma_l \Delta R_{t-l} + \Pi R_{t-1} + \varepsilon_t, \ \Pi = \alpha \cdot \beta' \qquad (2)$$

We tested whether products of nonstationary vector R_t and matrix Π, which contained cointegration vector, were stationary or not fewer than 5% of significance level.

It points out the robustness problems in conducting the Johansen test. One problem is related with choice of the lag length in VAR or ECM. It is the usual way to choose the lag length of VAR model or ECM according to the fitting criteria, e.g. Schwartz information criterion or others. It is true that these criteria are useful but may not indicate the number of lag-order to choose uniquely. Unfortunately, two models with different lag length bring us different results. It means that we may have two opposite implications for our investigations. Another problem in conducting the cointegration analysis is related with difficulties in identifying the proper rank of matrix Π and the appropriate equilibrium in the matrix β. When the Johansen test indicates the possibilities of the several cointegration vectors in the matrix β, which means that the number of the ranks r of matrix Π can be more than one, we may face the identification problem to choose the long run equilibrium.

In our empirical test, it is also important to investigate which error correction model with lags is fitter for the data generating processes and can bring each variable into appropriate long run equilibrium. Therefore, our attempts to improve the robustness were to carefully conduct the Johansen test with additional 8 tests as follows.

Firstly, we assumed the maxim lag-effect of the data generating process was 12 lags

and conducted the Johansen test for each model containing from 2 lags to 12 lags. Here we varied the sample period to equalize the degree of freedom in each of the 12 models. Secondly, we calculated the statistics of two information criteria: Schwartz information criterion and Hannan-Queen information criterion. Thirdly, we conducted the three kinds of tests for autocorrelations in the residuals of the ECM: Ljung-Box test on the estimated auto- and cross-correlations, LM-type test for the first and fourth order autocorrelations. These calculations and test statistics help us to choose lag order properly. At the fourth step, we conducted the additional three chi-square-based tests for each alpha or beta in matrix Π to avoid identification problems about the appropriate equilibrium. The first chi-square-based test will show whether each variable is excluded from the vector. The second one is to test whether the individual series are stationary by themselves. The last one is to test whether each variable can be considered weak exogenous or not. These three tests will be helpful for us not only to identify the long run equilibrium but also to choose proper lag length in the ECM. If we choose proper lag-order of the ECM, the null hypothesis of the second test must be rejected. If the second test shows the acceptance of null hypothesis of stationarity, it conflicts with the fact that each variable has unit root since we had already confirmed the nonstationarity of each variable with two kind of unit-root test. Therefore, the second test would help us to choose proper lag length in ECM. The other two tests also help to indicate the possibility of over-identification or under-identification. The first test will show the lack of needed variables in the model. Third one can indicate the existence of extra variables if we wrongly increase lag-order of the model.

In our arbitrary strategy improving the robustness, the point is that we should choose a lag length by taking into account whether the equilibrium of that model is adequate for the cointegration relationship or not. In other words, we investigated models that have an appropriate equilibrium in the data, and compared with the fitness of those models about lag-order. Our first step to choose ECM with proper lag order and appropriate long-run equilibrium is that we select the cases in which the assumption of no serial correlation about residuals holds. Next step is that we select the cases in which the chi-square-based tests show significance in the alternative hypothesis of the long-run exclusion, stationarity, and weak exogeneity. Final step is to make a comparison among all possible models in two information criterions. When we had more than two different results, we should compare the information criteria. Following these steps, we could uniquely define each ECM that included proper lag-order and appropriate equilibrium. We showed details of our strategy to define the unique model in the Appendix.

Table 1 shows maximum ranks, two kinds of information criteria, and three tests for residuals for each ECM from 2 to 12 lags. From the results of the Table 1, we could select a few or more cases from each set. Combining the results of the three chi-squared-tests for residual, we can find the most appropriate long-run equilibrium and lag-order from those cases. Then we conducted the three chi-square-based tests for each alpha or beta in matrix Π. We carefully chose the optimal error correction model with lags according to our strategy.

Next, Table 2 shows the result of Johansen test; □-trace and □-max tests after selecting the correct lag-order of all ECM. We had several cointegration relationships: 58 combinations for the US dollar as an anchor currency and 46 combinations for the common currency basket as an anchor currency.

Table 3 shows the result of three chi-square-based test identified as the optimal model. Here, we should only focus on the combinations in which all countries in a liner combination have significant results on those three tests, because we need to specify the minimal combination of currency area including all of the seven East Asian countries.

Empirical Results

For the US dollar, we could find only one combination in which all countries in a liner combination showed significant results on the three tests. This combination includes Singapore, Malaysia, Thailand, and Indonesia in the currency area (US409). For the common currency basket, we could find 9 combinations in which all countries in a liner combination showed significant results on the three tests. 4 of the 9 combinations include three East Asian countries in the currency area, Singapore, Thailand, and Indonesia (CB313), Singapore, Malaysia, and Thailand (CB315), Singapore, Thailand, and China (CB324), and Korea, Singapore, and China (CB335). The other 5 combinations include four East Asian countries in the currency area; Korea, Malaysia, the Philippines, and Indonesia (CB404), Korea, Singapore, Thailand, and Indonesia (CB406), Korea, Malaysia, Indonesia, and China (CB418), Korea, Singapore, Thailand, and China (CB426), and Singapore, Thailand, Indonesia, and China (CB428).

Our empirical results showed three features in comparing the US dollar with the currency basket as an anchor currency. First, while the common currency area evaluated by the US dollar as an anchor currency has only one combination, the common currency area evaluated by the currency basket as an anchor currency has several varieties of combinations. Second, some ASEAN countries can form a common currency area together with Korea or China with the currency basket as an anchor

currency while the common currency area with the US dollar as an anchor currency is limited to the four ASEAN countries. Third, for the currency basket as an anchor currency, we could find two different groups, whose countries include all of the East Asian countries but are not overlapped each other; the combination of Korea, Malaysia, the Philippines, and Indonesia (CB404) and the combination of Singapore, Thailand, and China (CB324). We could not find the two groups when we test possibility of the common currency area by the US dollar as an anchor currency. From these features, our empirical results suggest that the common currency basket is more applicable for an anchor currency than the US dollar when East Asian countries form a common currency area in the region.

Policy implications

Among the findings, the third one implies that the two non-overlapping groups will be able to form a larger common currency area by their inter-group policy coordination. Eventually, adjustment speeds toward the long run equilibrium are different between the two groups while the two groups can share the same basket weights. The equilibrium defined by our G-PPP model can be interpreted as the balance of payments equilibrium for a total of the common currency area countries. If the two groups have different adjustment speeds toward the long run equilibrium, there is a possibility that one group may run current account surplus in total while the other may run current account deficit in total during the adjustment process toward the long run equilibrium. Our empirical results suggested that the combination which includes all the seven countries could not be stable in the long run while the two non-overlapping combinations had cointegration relationships when both of the two combinations used the common currency basket as an anchor currency. It means that each of the two groups will be able to create a different common currency area by using a common currency basket and the same basket weights at the same time. However, in the adjustment process toward the long run equilibrium the two groups may face a currency account deficit or surplus. In this case, governments included in the two common currency area need to make a policy coordination between the two groups, that is called an "inter-group policy coordination". We suggest that the key feature of the "inter-group policy coordination" is to employ macroeconomic policies including fiscal policy or fiscal transfers to adjust the transitional asymmetry in the balance of payment between two groups during adjustment process. In addition to the inter-group policy coordination, we can suggest that deepening of the financial integration or structural economic

integration in East Asia may help to equalize the different adjustment speeds between the two groups.

Conclusion

This paper suggested that it is necessary to create a common currency basket in order to resolve coordination failure in choosing desirable exchange rate system for East Asian countries. From this point of view, it is natural that a future regional currency arrangement in East Asia should be related with a common currency basket. The European experiences of the ECU should provide us with useful information in considering a common currency unit in East Asia. In the case of East Asian countries, we have international trade relationship with variety of regions that include the intra-region, Japan, the United States, and European countries. Therefore, a possible common currency unit in East Asia would consist of the US dollar, the Japanese yen, and the euro and so on. It is contrast with the ECU case where the ECU consisted of intra-regional currencies.

We used the Generalized Purchasing Power Parity (G-PPP) model to investigate possibilities of a common currency area for some of East Asian countries in terms of a long-run stable linear combination among some regional currencies. The analytical results imply that the ASEAN5 countries, China, and Korea will be candidates for a common currency area with a common currency basket as an anchor currency. Also, we have a conclusion that a common currency basket is more applicable for an anchor currency than the US dollar in forming a common currency area in the region.

However, it may be questionable to establish a currency union in East Asian region in the near future. We can point out that possibilities of regional policy coordination depend on consensus of policy objectives among the governments of East Asian countries. Needless to say, the monetary authorities have to intend to make regional policy coordination as a premise that they create a common currency area. It is difficult for them to make regional policy coordination unless they have common policy objectives. Especially, it is important that they have common objectives in monetary and exchange rate policies in order to create a common currency area.

Appendix:

The cointegration analysis is a very useful tool to investigate the dynamic path of the multiple economic variables. However, it is susceptible (subject) to criticism

regarding the robustness of the test results. Namely, the number of cointegration relationships (the cointegration rank) sometimes varies with the lag order of the underlying vector-autoregressive model. If the rank condition is variable, we have a lot of possibilities to identify equilibrium among variables. That is, two issues: whether or not the long run relationship among variables can be present in the data and which equilibrium has more important implication for economics, depend on our choice of the lag order. Therefore, we need to carefully identify the appropriate error correction model before conducting the Johansen test.

In this paper, we provisionally introduce additional 8 tests into Johansen cointegration analysis to solve "the dilemma" problem. The point is that we choose the lag order of error correction model considering the appropriate equilibriums and elements in matrix Π. In other words, we first investigate an appropriate equilibrium of those variables, and test whether that equilibrium and the resultant error correction model satisfy the several assumptions of the Johansen test. Our assumptions are that (1) there is no serial correlation in residuals of the VAR models, (2) each variable could be included in the long run relationship, (3) each variable is nonstationary, and (4) each variable is an endogenous variable in their relationship. If we could find the true data generating process between variables, and it has a long run equilibrium to converge, that model must fulfill all our assumptions of the cointegration analysis. In the case that there is no equilibrium that meets our assumptions, we can recognize that there is no long-run relationship at all between variables, and the cointegration rank must be zero. Depending upon the lag order, we may encounter conflicting results: one result is that there is at least one cointegration and the other is that there is no cointegration, but in both instances the assumptions of the Johansen procedure are satisfied. To choose between the two, we examine the fitness of the alternative models by applying the conventional information criteria. Our empirical strategy is as follows.

Prior to cointegration analysis, we have to confirm whether or not each variable has a unit root and is nonstationary. In some cases, stationary series can be included in cointegration relationship or error correction model. But in our G-PPP model, we assume all variables to be nonstationary.

(Step 1) We conduct the Johansen test for VAR models. Here, we conduct the tests for the 11 sets of error correction model with lag order from 2 to 12 per one linear combination of variables and varied the sample period to equalize the degree of freedom in each of the 12 models. We assume that maximum lag order effecting on the equilibrium is 12 in the true data generating process. This assumption can easily be changed.

(Step 2) Next, we calculate three test statistics for residuals: multivariate Ljung-Box test based on the estimated auto- and cross-correlations of the first quarter number of lags of all sample periods, Lagrange-Multiplier type tests for first and fourth order autocorrelations. The residuals of VAR or error correction model are assumed to have no serial correlation. Therefore, we exclude the cases where the assumption is not met regardless of whether cointegration rank is zero or not.

Here, we gather the cases which validate the assumption of no serial correlations in residuals. We can divide those models into a group of no cointegration rank and that of more than one. If there are some cases that cointegration rank is more than one, which means there are more equilibria between variables, we have to conduct the further tests for these cases.

(Step 3) We conduct three kinds of chi-square-based tests for the cases which have equilibrium. Usually, these tests are used for identifying the equilibrium. We use these tests not only to identify the equilibrium but also to choose a proper lag order. The first test is to find variables than can be excluded from the long run relationship in the cointegrating vector R. The null hypothesis in this test is $\beta_{ij} = 0$. If the null is accepted and the test statistic is asymptotically distributed as chi-square with r degrees of freedom, it might mean the possibilities that some relevant variables are missing from the cointegration relationship. In the case of strong multicollinearity, we will also get an insignificant test value. The second test is about stationarity. This test is to check whether the individual series can be stationary by themselves. The null is $\beta = (H_i, \varphi)$. If the null is accepted and the test statistic is asymptotically distributed as chi-square with r degrees of freedom, it might mean the possibility that the variable will be excluded from the cointegration relationship; therefore we can identify the minimal set of variables that comprise the long-run equilibrium relationship. The last is to test whether any of the elements in the vector R can be considered as weakly exogenous for the long run equilibrium. The null hypothesis is $\alpha_{ij} = 0$. In the case of accepting the null and asymptotically distributed as chi-square with r degrees of freedom, that variable might be a weakly exogenous series for the long rung equilibrium, therefore, we can exclude such cases.

If all three tests are passed here, we can find the minimum set of variables in the long-run equilibrium. Therefore, for most cases, we can identify optimal error correction model with proper lags and appropriate equilibrium to converge. We can call this the "Best fitting model". If we cannot find any cases which satisfy the three tests, we should focus on the second best case. We regard the second best cases to be those which meet the stationarity test, but fail to pass the other two tests. We should not jump to a

conclusion of no linear long-run equilibrium. The first and third tests are very helpful for us because these tests can detect the possibilities of over-identification or under-identification of model not only for the minimum set of variables but also for the proper lag length. When we wrongly increase the lag length or erroneously determine the rank, test statistics suddenly show the possibilities of accepting the null. On the other hand, we may be able to find some other exogenous variables to form a long-run equilibrium relationship as an exogenous variable. Therefore, we have to carefully look into a second best. Here, we only focus on the cases in which at least two variables in the vector can be rejected the null of long-run exclusion and weak exogeneity because it is not important to think that only one endogenous variable with several exogenous variables can converge to long run equilibrium in a common currency area or G-PPP model.

(Step 4) We compare all possible models in terms of the fitness of true data generating process. This step is helpful to avoid the arbitrariness to choose a model in final step. In step 3, we may not be able to find the best case and may have to look for second best cases. It is true that the first test and the third one indicate the possibility of over- or under-identification of model, but we cannot fully identify it. It means that we cannot recognize whether or not that model is more suitable than other. Therefore, in the final step, we use information criterion to choose proper or fitting model for data generating process. According to these steps, we can identify the unique model and equilibrium.
