Running title: P4-ATPases drive membrane curvature

Keywords: plasma membrane, lipid, flippase, BAR domain, curvature

Abstract

P4-ATPases are phospholipid flippases that translocate phospholipids from the exoplasmic/luminal to the cytoplasmic leaflet of biological membranes. All P4-ATPases in yeast and some in other organisms are required for membrane trafficking; therefore, changes in the transbilayer lipid composition induced by flippases are thought to be crucial for membrane deformation. However, it is poorly understood whether the phospholipid-flipping activity of P4-ATPases can promote membrane deformation. In this study, we assessed membrane deformation induced by flippase activity via monitoring the extent of membrane tubulation using a system that allows inducible recruitment of Bin/Amphiphysin/RVS (BAR) domains to the plasma membrane (PM). Enhanced phosphatidylcholine-flippase activity at the PM due to expression of ATP10A, a member of the P4-ATPase family, promoted membrane tubulation upon recruitment of BAR domains to the PM. This is the important evidence that changes in the transbilayer lipid composition induced by P4-ATPases can deform biological membranes.

Introduction

P4-ATPases flip phospholipids across the bilayer to generate and regulate the asymmetric distributions of lipids in eukaryotic cells. Phosphatidylserine (PS) and phosphatidylethanolamine (PE) are enriched in the cytoplasmic leaflet of the plasma membrane

(PM), whereas phosphatidylcholine (PC) and sphingomyelin are abundant in the exoplasmic leaflet (Devaux, 1991, Murate *et al.*, 2015, Zachowski, 1993). Genetic studies in *Saccharomyces cerevisiae*, *Arabidopsis thaliana*, and *Caenorhabditis elegans* revealed that P4-ATPases play roles in membrane trafficking. All five yeast P4-ATPases are involved in membrane trafficking at different stages of the secretory and endocytic pathways (Graham & Burd, 2011, Muthusamy *et al.*, 2009). In addition, PS flipping at the *trans*-Golgi network participates in exocytic protein sorting and enhances membrane curvature in yeast (Chen *et al.*, 1999, Hankins *et al.*, 2015, Xu *et al.*, 2013). The human genome encodes 14 P4-ATPases; however, their functions are poorly understood (Andersen *et al.*, 2016). Among mammalian P4-ATPases, ATP8A1 and ATP9A are required for endosome-mediated membrane trafficking, and PS flipping by ATP8A1 is needed for recruitment of EHD1 to recycling endosomes (Lee *et al.*, 2015, Tanaka *et al.*, 2016). Therefore, the activities of P4-ATPases seem to be required for the recruitment of proteins involved in membrane trafficking to cellular compartments. Another plausible hypothesis is that P4-ATPase-mediated phospholipid translocation generates an imbalance in the level of lipids between the leaflets of the bilayer. The resultant lipid-loading in the cytoplasmic leaflet would drive inwardly directed membrane deformation, leading to the membrane curvature required for vesicle budding (Graham, 2004, Panatala *et al.*, 2015, Takeda *et al.*, 2014). Cell shape drastically changes upon exogenous application of lyso-PC or impermeable amphipathic drugs, suggesting that the shape of lipid species and/or an imbalance in lipid mass (translocation of lyso-PC is much slower than that of PC) are involved in the generation of membrane curvature (Devaux *et al.*, 2008, Sheetz & Singer, 1974). Changes in lipid composition following addition of exogenous phospholipids alter the shape of erythrocytes, and it was thus hypothesized that ATP-dependent lipid translocases at the PM are involved in membrane shape changes (Daleke & Huestis, 1989, Seigneuret & Devaux, 1984). We and other groups have recently shown the flippase activities of mammalian P4-ATPases (Lee *et al.*, 2015, Naito *et al.*, 2015, Segawa *et al.*, 2016, Takatsu *et al.*, 2014, Zhu *et al.*, 2012) using a cell-based flippase assay. However, it remains unknown whether flippase activity of P4-ATPase family can induce membrane curvature because spatiotemporal flippase activity cannot be visualized together with membrane deformation in biological membranes. To overcome this technical problem, we designed an experiment to indirectly assess membrane deformation induced by flippase activity in the PM.

We have previously shown that enhanced PC-flippase activity at the PM changes cell shape, decreases cell size, and delays cell spreading on extracellular matrix, possibly by increasing inwardly directed PM bending (Miyano *et al.*, 2016, Naito *et al.*, 2015). Therefore,

spatiotemporally regulated movement of lipids between the leaflets of the bilayer could contribute to PM remodeling. In fact, a mutation in the mouse *ATP11C* gene, another member of the P4-ATPase family, alters the morphology of erythrocytes (Yabas *et al.*, 2014), and a complex comprising ATP8A1 and CDC50A has been implicated to play a role in cell migration (Kato *et al.*, 2013). CDC50A interacts with most P4-ATPases and is required for the transport of newly synthesized P4-ATPases from the endoplasmic reticulum to cellular compartments and/or the PM (Naito *et al.*, 2015, Takatsu *et al.*, 2011).

To investigate whether a lipid imbalance in the bilayer induced by P4-ATPases is directly linked with membrane curvature, we used BIN/Amphiphysin/Rvs (BAR) domains, which dimerize to form a crescent-shaped structure, sense membrane curvature, and generate tubular membrane structures via self-oligomerizing in biological membranes (Frost *et al.*, 2008, Itoh & De Camilli, 2006, Peter *et al.*, 2004, Yin *et al.*, 2009). BAR domains are categorized into four main subfamilies: classic BAR, N-terminal amphipathic helix-containing BAR (N-BAR), Fes-CIP4 homology BAR (F-BAR), and inverse BAR (I-BAR) (Frost *et al.*, 2009, Itoh & De Camilli, 2006). These domains mediate membrane curvature by performing scaffolding roles and/or inserting amphipathic helices along lipid bilayers, and form membrane tubules in cells and artificial liposomes (Bhatia *et al.*, 2009, Gallop *et al.*, 2006, Masuda *et al.*, 2006, Poudel *et al.*, 2016).

Membrane deformation/tubulation induced by BAR domains from the PM has been visualized using a chemically inducible dimerization (CID) technique that allows acute recruitment of these domains to the PM (Komatsu *et al.*, 2010, Suarez *et al.*, 2014). The PM-recruited N-BAR domain induces dramatic membrane tubulation from the PM (Suarez *et al.*, 2014). By striking contrast, the Δ N-BAR domain, which lacks the N-terminal amphipathic helix of the N-BAR domain and thus is structurally similar to classic BAR domains, and the F-BAR domain rarely promote the formation of membrane tubules from the PM (Suarez *et al.*, 2014), although classic BAR and F-BAR domains can induce membrane tubule formation from liposomes (Henne *et al.*, 2007, Peter *et al.*, 2004). The amphipathic helix of the N-BAR domain penetrates the lipid bilayer, leading to increased membrane curvature into the cytoplasm, and the BAR domain subsequently senses this curvature and drives membrane tubule formation (Figure 8A) (Campelo *et al.*, 2008, Gallop *et al.*, 2006, McMahon & Boucrot, 2015, Poudel *et al.*, 2016). Therefore, we hypothesized that if proper membrane curvature is generated, the Δ N-BAR and/or F-BAR domains should be able to induce the generation of membrane tubules from the PM in the same way as the N-BAR domain does. We assessed membrane curvature

induced by flippase activity via monitoring the extent of membrane tubulation using the CID technique that allows acute recruitment of BAR domains to the PM.

Results and Discussion

Recruitment of the N-BAR domain, but not of the Δ N-BAR or F-BAR domain, to the PM induces the generation of membrane tubules from the PM.

We transfected HeLa cells with two constructs: fluorescent protein-fused PM-targeting FRB [FK506-binding protein (FKBP)-rapamycin-binding domain] and fluorescent protein-fused FKBP-BAR domains (Figure EV1A). TagBFP2- or TagRFP-tagged FRB was targeted to the PM by adding the N-terminal 11 amino acids (a.a.) of Lyn, and EGFP- or mCherry-tagged FKBP was fused to each BAR domain [N-BAR (N-BAR domain of human amphiphysin 1), Δ N-BAR (lacking the N-terminal amphipathic helix of the N-BAR domain), or F-BAR (F-BAR domain of formin-binding protein 17, FBP17)] (Suarez *et al.*, 2014). The morphology of the PM was visualized by confocal or epifluorescence microscopy, as shown by fluorescent signals of the PM-targeting FRB and FKBP-BAR domains, following treatment with rapamycin, which triggers heterodimerization of FRB and FKBP (Figure EV1A). In the absence of rapamycin, all FKBP-BAR domains, as well as EGFP-FKBP, were predominantly distributed throughout the cytoplasm, and PM-targeting FRB was localized at the PM as described previously (Figure EV1B–D, a and c, Movies EV1–EV4) (Suarez *et al.*, 2014). Upon treatment with rapamycin, the FKBP-BAR domains and EGFP-FKBP were rapidly recruited to the PM (Figure EV1B–D, b–b'' and d–d'', Movies EV1–EV4). The CID-engineered N-BAR domain rapidly induced dramatic formation of tubular structures from the PM (Figure EV1B b–b'' and d–d'', Movie EV2, Figure 8) (Suarez *et al.*, 2014, Yin *et al.*, 2009). These tubular structures did not colocalize with markers of endosomes or the Golgi complex (Figure EV1E); therefore, it is unlikely that they were generated from these intracellular compartments. By contrast, the CID-engineered Δ N-BAR and F-BAR domains, as well as EGFP alone, failed to induce membrane tubulation from the PM, even if they were efficiently recruited to the PM upon rapamycin treatment (Figure EV1C and D, b–b'' and d–d'', Movies EV1, EV3, and EV4) (Suarez *et al.*, 2014). Thus, penetration of the amphipathic helix of the N-BAR domain may have a wedging effect, leading to increased curvature of the PM into the cytoplasm, and the BAR domain may subsequently sense this membrane curvature and drive membrane tubulation via oligomerizing along the membrane (Figure 8A) (Campelo *et al.*, 2008, Gallop *et al.*, 2006, Poudel *et al.*, 2016).

Recruitment of the Δ N-BAR or F-BAR domain to the PM leads to the generation of membrane tubules in cells stably expressing ATP10A

We previously showed that ATP10A localizes at the PM and exhibits relatively high PC-flipping activity, and that its exogenous expression changes cell shape and delays cell adhesion and cell spreading on the extracellular matrix (Miyano *et al.*, 2016, Naito *et al.*, 2015). PC is primarily enriched in the exoplasmic leaflet of the PM (Murate *et al.*, 2015). Thus, increased PC-flippase activity due to ATP10A expression allows continuous and excessive phospholipid flipping from the exoplasmic to the cytoplasmic leaflet, resulting in changes in cell shape, decreases in cell size, and delays in cell spreading (Miyano *et al.*, 2016, Naito *et al.*, 2015). ATP10A is not expressed in HeLa cells (Takatsu *et al.*, 2011) (Figure EV4A), and thus its expression may have marked effects on these cells. We hypothesized that ATP10A expression might trigger inward bending of the PM, thereby promoting membrane tubulation induced by PM-recruited BAR domains. To test this hypothesis, we used HeLa cells stably expressing ATP10A; the ATP10A(E203Q) mutant, which lacks ATPase activity; and ATP11A, which specifically flips PS/PE at the PM (Takatsu *et al.*, 2014) (Figure 1). The expression level of ATP10A was comparable to that of ATP10A(E203Q) and lower than that of ATP11A (Figure EV2A), and PC-flippase activity was not altered upon rapamycin treatment (Figure EV2B). We also confirmed that the PC-flippase activity of ATP10A was not altered upon expression of BAR domains or their recruitment to the PM (Figure EV2C).

Recruitment of the Δ N-BAR or F-BAR domain to the PM did not cause membrane tubulation in parental HeLa cells (Figures EV1C and D). By contrast, recruitment of the Δ N-BAR or F-BAR domain to the PM induced drastic membrane tubulation in cells expressing ATP10A (Figure 1A and D, b, b', d, and d', Movies EV5, EV6, EV9, and EV10), but not in cells expressing ATP10A(E203Q) (Figure 1B and E, b, b', d, and d', Movie EV7). These results demonstrate that the PC-flippase activity of ATP10A mediates membrane tubule formation. Recruitment of the N-BAR domain to the PM caused membrane tubulation in parental HeLa cells as well as cells expressing ATP10A, ATP10A(E203Q), and ATP11A (Figure 1G-I, b' and d' and Figure EV1B). No tubular membrane structures were observed in cells not treated with rapamycin (Figure 1A, D, and G, a and c, Movies EV5 and EV6). For semi-quantitative analysis, we counted the numbers of cells containing tubular membrane structures following rapamycin treatment. Recruitment of the Δ N-BAR or F-BAR domain to the PM in ATP10A-expressing cells increased the proportion of cells containing tubular structures relative to

control and ATP10A(E203Q)-expressing cells (Figure 1J and K). Although the PM-recruited N-BAR domain drove membrane tubulation in parental HeLa cells (Figure EV1B, Figure 1L (-)), the number of cells containing tubular structures was slightly higher among those expressing ATP10A, but not among those expressing ATP10A(E203Q) or ATP11A (Figure 1L).

The PM-recruited Δ N-BAR and F-BAR domains did not cause membrane tubulation in cells expressing ATP11A, which flips PS/PE at the PM (Takatsu *et al.*, 2014) (Figure 1C and F, b, b', d, and d'). The level of PS/PE is limited in the exoplasmic leaflet (Murate *et al.*, 2015, Op den Kamp, 1979); therefore, exogenous expression of ATP11A may not trigger membrane deformation. Therefore, excessive PC flipping from the outer to the inner leaflet driven by ATP10A generates membrane curvature by inducing an imbalance of lipid mass between the two leaflets.

Disruption of cytoskeleton leads to a reduction in membrane tension that can initiate membrane tubulation mediated by an N-BAR domain-containing protein (Gauthier *et al.*, 2012, Masters *et al.*, 2013, Shi & Baumgart, 2015). We therefore investigated whether this membrane tubulation, which is induced by BAR domains in ATP10A-expressing cells, is caused by disruption of cytoskeleton. The integrity of the actin cytoskeleton and microtubules was not affected by expression of ATP10A or recruitment of the Δ N-BAR domain to the PM in ATP10A-expressing cells in comparison with control cells (Figure 2A and B, a, a', d, d', g, and g'). These results suggest that enhanced PC-flipping activity increases inward bending of the PM and generates membrane curvature. Thus, the PM-recruited Δ N-BAR and F-BAR domains stably interact with curved membranes, resulting in membrane tubulation from the PM.

Disruption of microtubules attenuates membrane tubulation caused by BAR domains

We next asked whether the membrane tubulation generated by the recruitment of BAR domains to the PM is dependent on microtubules. To this end, we treated cells with nocodazole to disrupt microtubules (Figure 3A–D, d). We confirmed that nocodazole treatment did not affect the flippase activity of ATP10A (Figure EV2D). Nocodazole treatment reduced the formation of tubular membrane structures by PM-recruited N-BAR domain (Figure 3A e–f', and E). In addition, membrane tubules generated by PM-recruited Δ N-BAR or F-BAR domain in ATP10A-expressing cells were also reduced by treatment with nocodazole (Figure 3C and D, e–f', and F and G). Therefore, the membrane tubulation by the BAR-domains was in a

manner dependent on microtubules. Although cell populations containing long tubular structures were reduced upon nocodazole treatment (Figure 3E–G), very short tubules were observed (Figure 3A and C, e'' and f'') suggesting the possibility that elongation of membrane tubules require the integrity of microtubules.

An increase in PM tension prevents the generation of membrane tubules by BAR domains

We next investigated whether inward bending of the PM is a prerequisite for membrane tubulation driven by PM-recruited BAR domains. To this end, we examined whether an increase in PM tension inhibited BAR domain-driven membrane tubulation by exposing cells to hypotonic medium (Figures 4 and 5). Intriguingly, recruitment of the N-BAR domain to the PM did not induce membrane tubulation in cells exposed to hypotonic conditions (Figure 4A e–f' and E, Movies EV2 and EV8). Cells were exposed to hypotonic medium before or after treatment with rapamycin (Movie EV8 and EV2, respectively) and cells did not generate membrane tubules in either case. Upon exposure to hypotonic conditions, cells swelled acutely (Movies EV2, EV5, and EV8), indicating that PM tension was increased. These results suggest that outward swelling of cells negatively affects membrane curvature toward the cytoplasm. We next investigated whether a decrease in membrane tension triggers membrane tubulation by exposing cells to hypertonic medium. However, hypertonic stress did not significantly affect membrane tubulation driven by the N-BAR domain (Figure 4B e–f' and F) or trigger membrane tubulation driven by the Δ N-BAR domain (Figure 4D e–f' and G). Thus, even in shrunken cells exposed to hypertonic medium, the PM may not bend properly to allow the Δ N-BAR domain to form membrane tubules.

Exposure to hypotonic medium also abrogated membrane tubulation induced by the PM-recruited Δ N-BAR and F-BAR domains in ATP10A-expressing cells (Figure 5A and C, e–f', E, F, Movie EV5). Membrane tubules induced by the PM-recruited Δ N-BAR domain was readily disappeared upon exposure to hypotonic medium (Movie EV5), suggesting that tubular structures are highly dynamic and susceptible to a change in membrane tension. Thus, outward swelling of cells prevents inward PM bending triggered by the flippase activity of ATP10A and by insertion of the amphipathic helix of the N-BAR domain. Notably, the PC-flippase activity of ATP10A was abrogated under hypotonic conditions (Figure EV2D). Therefore, we cannot exclude the possibility that ablation of membrane tubules upon hypotonic stress is associated with the lack of flippase activities. However, we think that the disappearance of membrane tubules under hypotonic condition is due to the increase in membrane tension which

prevents inward PM bending, because the N-BAR domain did not generate membrane tubules (Figure 4A). Exposure to hypertonic medium did not affect membrane tubulation driven by the Δ N-BAR or F-BAR domain in ATP10A-expressing cells (Figure 5B and D, e–f). This result corresponds to the membrane tubulation driven by the N-BAR domain (Figure 4B and F). Membrane tubulation was not observed in ATP10A(E203Q)-expressing cells under any condition (Figure EV3).

Depletion of ATP10A inhibits membrane tubulation induced by the Δ N-BAR and F-BAR domains in cells stably expressing exogenous ATP10A

To confirm that the flippase activity of ATP10A is indispensable for deformation of the PM, we knocked down ATP10A via RNAi in cells stably expressing this flippase. Efficient knockdown of ATP10A was confirmed by immunoblot analysis (Figure EV4B), measurement of PC-flippase activity (Figure EV4C), and immunofluorescence analysis (Figure 6A, C, and E, k and l). Membrane tubulation driven by recruitment of the Δ N-BAR and F-BAR domains to the PM was significantly decreased in ATP10A-depleted cells (Figure 6A and C, h, h', j, and j', B, and D). These results revealed that membrane tubulation induced by the Δ N-BAR and F-BAR domains in ATP10A-expressing cells is due to increased PC-flippase activity at the PM. Membrane tubulation induced by the N-BAR domain was not decreased in ATP10A-depleted cells (Figure 6E h, h', j, and j', and F), probably due to its high membrane-deforming activity and/or a modest level of residual ATP10A protein (Figure EV4B).

Enhanced PC-flipping activity increases endocytosis of β 1-integrin

Since incubation with phospholipids, but not lyso-phospholipids, enhances endocytosis in K562 cells (Farge *et al.*, 1999), it was hypothesized that phospholipid treatment increased the concentration of phospholipids in the inner leaflet of the PM and endocytosis was subsequently enhanced. We examined whether increased flippase activity upon ATP10A expression facilitates endocytosis. To this end, β 1-integrin internalization was examined by following an extracellularly applied anti- β 1-integrin antibody (Figure 7A). Cells were incubated with an anti- β 1-integrin antibody at 4°C for 1 h, washed with ice-cold PBS to remove unbound antibodies, and incubated at 37°C for the indicated durations to allow the internalization of β 1-integrin (Figure 7). Cells were then washed with acidic solution to remove residual antibodies on the PM. The fluorescence intensity of intracellular β 1-integrin was estimated in cells expressing ATP10A and ATP10A(E203Q) and parental cells. Internalization of β 1-integrin

was significantly increased at 15 and 30 min in cells stably expressing ATP10A, but not in those stably expressing ATP10A(E203Q) (Figure 7B). In addition, the internalization was not altered in cells stably expressing ATP11A as compared with control cells (Figure 7B). As we discussed above, the level of PS/PE is limited in the exoplasmic leaflet (Murate *et al.*, 2015, Op den Kamp, 1979); therefore, exogenous expression of ATP11A may not trigger the phospholipids imbalance and membrane deformation. Therefore, enhanced inward bending of the PM induced by ATP10A expression facilitates the internalization of β 1-integrin, which may delay cell adhesion and cell spreading on extracellular matrix (Miyano *et al.*, 2016, Naito *et al.*, 2015). We also recognized that ATP1A1 (Na/K pump), which mainly localizes to the PM, appeared more frequently in intracellular puncta in cells expressing ATP10A than in control cells (Figure EV5A). Counting of cells in which ATP1A1 localized to the PM, and the PM and cellular puncta revealed that intracellular ATP1A1 was substantially increased in cells expressing ATP10A but not ATP10A(E203Q) (Figure EV5B) suggesting that ATP10A expression increased the internalization of ATP1A1.

Then we asked whether depletion of endogenous ATP10A affects the β 1-integrin endocytosis. To this end, we depleted ATP10A by CRSIPR/Cas9 system in MDA-MB-231 cells which express endogenous ATP10A (Figures EV4A, and EV6A and B) and examined the β 1-integrin internalization in the knockout cells. As shown in Figure EV6, although knockout of endogenous ATP10A tended to decrease the endocytosis of β 1-integrin, the decrease was not statistically significant (Figure EV6C). One possibility would be a functional redundancy of other PC-flippases because MDA-MB-231 cells express PC-flippases such as ATP8B1 and ATP8B2 (Takatsu *et al.*, 2014) (Figure EV6D).

Taken together, these results strongly suggest that enhancement of PC-flipping in ATP10A-expressing cells induces an imbalance in the level of lipids between the leaflets of the bilayer and increases inward PM bending, driving membrane curvature and allowing membrane tubulation by BAR domains, even those that lack the N-terminal amphipathic helix. Given that an increase in PM tension following hypotonic treatment suppressed membrane tubulation driven by the N-BAR domain in parental HeLa cells, as well as by the Δ N-BAR and F-BAR domains in ATP10A-expressing cells, membrane curvature induced by the N-terminal amphipathic helix of N-BAR or enhanced PC-flippase activity (Figure 8A and B) is a prerequisite for membrane tubulation. PC is abundant in the outer leaflet of the PM; therefore, enhanced PC flipping by ATP10A most likely causes a lipid imbalance. On the other hand, PS/PE is confined to the inner leaflet of the PM, meaning that expression of ATP11A may not

generate a lipid imbalance to allow membrane deformation. Notably, phospholipid flipping at the PM was generally suppressed in hypotonic conditions but not in hypertonic conditions (Figure EV2D). This suggests that an acute increase in membrane tension inhibits not only membrane bending but also transbilayer lipid translocation.

In yeast, inactivation of Drs2p, a Golgi-localized PS-flippase, inhibits recruitment of Arf-GTPase-activating protein (Gcs1p) to Golgi and endosomal membranes. Gcs1p contains an amphipathic, α -helical ArfGAP lipid packing sensor (ALPS) motif, which plays a critical role in recruitment of Gcs1p to membranes by sensing membrane curvature. Therefore, the PS-flippase activity of Drs2p may be required to generate membrane curvature, which allows the recruitment of Gcs1p to membranes (Xu *et al.*, 2013). Indeed, yeast cells depleted of Drs2p accumulated aberrant membrane structures (Chen *et al.*, 1999). There are other explanations for these observations, such as an electrostatic interaction between Gcs1p and PS. While this study provides evidence for an effect of transbilayer lipid-mass changes on membrane deformation since electrostatic effects on the PM can be excluded because PC is a neutral phospholipid. In addition, phospholipid flipping itself, regardless of which phospholipid is flipped, seems to be required for vesicle formation in yeast (Takeda *et al.*, 2014). Together with our findings, phospholipid-flipping activities of P4-ATPases are able to induce membrane curvature by generating an imbalance in the level of lipids between the two leaflets of the PM and other cellular compartments, regardless of the flipped phospholipid species. The data presented herein provide the important experimental evidence that phospholipid-flippase activity can deform biological membranes. This raises questions when, where, and how flippases can act. We recently have revealed the signal-dependent regulation mechanism of ATP11C, a PS-flippase (Takatsu *et al.*, 2017). Elucidation of regulation mechanisms of P4-ATPases including PC-flippases enable understanding of how P4-ATPases play roles in many cellular processes involving membrane deformation, including membrane trafficking and cell migration.

Materials and Methods

Plasmids

Constructs for C-terminally HA-tagged P4-ATPases were generated as described previously (Takatsu *et al.*, 2011, Takatsu *et al.*, 2014). Constructs for FKBP-conjugated fluorescent N-BAR (human amphiphysin 1, a.a. 1–248), Δ N-BAR (a.a. 26–248), F-BAR (human FBP17, a.a. 1–300), and FRB-conjugated Lyn (a.a. 1–11) were obtained as described

previously (Komatsu *et al.*, 2010, Suarez *et al.*, 2014). DNA fragments of Lyn-mCherry-FRB were amplified by PCR and inserted into pcDNA3 using the *EcoRI* and *XhoI* sites. Thereafter, DNA fragments encoding TagBFP2 (Evrogen) and TagRFP (a kind gift from Hideki Shibata, Nagoya University) (Shibata *et al.*, 2010) were amplified and inserted in place of mCherry cDNA at the *AgeI* and *BsrGI* sites using an In-Fusion HD cloning kit (Clontech). To construct Lifeact-EGFP and Lifeact-mCherry, sense and antisense oligonucleotides corresponding to the first 17 a.a. of Abp140 (Riedl *et al.*, 2008) were synthesized, annealed, and inserted into pEGFP-N1 (Invitrogen) and pcDNA3-mCherry-N (a kind gift from Roger Tsien, University of California).

Cell culture, siRNA-mediated knockdown, and transfection

HeLa cells were cultured in Minimal Essential Medium (MEM) supplemented with 10% heat-inactivated fetal bovine serum (FBS) at 37°C in 5% CO₂. Cells stably expressing HA-tagged P4-ATPases were generated as described previously (Naito *et al.*, 2015, Takatsu *et al.*, 2014). HeLa cells were transfected with plasmids carrying each FKBP-fused fluorescent BAR domain and FRB-fused fluorescent Lyn using X-tremeGENE9 (Roche Applied Science).

siRNAs were prepared as described previously (Naito *et al.*, 2015). In brief, pools of siRNAs targeting the coding region of human ATP10A (nucleotides 655–1399 of ATP10A mRNA; the A nucleotide of the ATG initiation codon was defined as nucleotide 1) were prepared using the T7 RiboMAX Express RNAi System (Promega) and PowerCut Dicer (Fynzymes). Cells were transfected with siRNAs using Lipofectamine 2000 (Invitrogen) and incubated for 24 h. Transfected cells were seeded onto culture dishes. After 24 h, cells were transfected with the siRNAs again and incubated for an additional 24 h. Finally, transfected cells were transferred to new culture dishes containing coverslips, incubated for an additional 48 h, and processed for immunoblot and immunofluorescence analyses.

Antibodies and reagents

Antibodies were obtained from the following sources: monoclonal mouse anti- β -tubulin (KMX-1) (Millipore); monoclonal mouse anti-EEA1 (clone 14), anti-Lamp-1 (H4A3), anti-SNX1 (clone 51), anti- β 1-integrin (Mab13), and anti-GM130 (BD Biosciences); monoclonal rat anti-HA (3F10; Roche Applied Science); monoclonal rabbit anti-ATP1A1 (EP1845Y) (Abcam); Alexa Fluor-conjugated secondary antibodies (Molecular Probes); and Cy3- and horseradish peroxidase-conjugated secondary antibodies (Jackson ImmunoResearch

Laboratories). Alexa Fluor 488- and 555-conjugated phalloidin was purchased from Molecular Probes. The NBD-labeled phospholipids (Avanti Polar Lipids) used in this study were NBD-PS (1-oleyl-2-[6-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]hexanoyl]-sn-glycero-3-phosphoserine), NBD-PE (1-oleyl-2-[6-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]hexanoyl]-sn-glycero-3-phosphoethanolamine), and NBD-PC (1-oleyl-2-[6-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]hexanoyl]-sn-glycero-3-phosphocholine. Nocodazole, rapamycin, and fibronectin were obtained from Sigma-Aldrich and LC Laboratories, respectively.

Immunofluorescence and live-cell imaging

Cells grown on coverslips were treated with 200 nM rapamycin for 15 min, 16.7 μ M of nocodazole for 60 min, hypotonic medium (10% MEM and 90% H₂O) for 15 min, or hypertonic medium (MEM containing 200 mM sucrose) for 20 min. Time schedule for the treatment(s) was shown in table EV. Treated cells were fixed with 3% paraformaldehyde in PBS at 37°C for 15 min, permeabilized with 0.1% Triton X-100 at room temperature for 5 min, and incubated in PBS containing 10% FBS at room temperature for 30 min. Cells exposed to hypotonic or hypertonic medium were fixed with 3.7% formaldehyde prepared in 0.1 $\times$ PBS or 3.7% formaldehyde prepared in 1 $\times$ PBS containing 200 mM sucrose, respectively. Fixed cells were incubated with primary antibodies at room temperature for 1 h, washed three times with PBS, and incubated with secondary antibodies at room temperature for 1 h. Coverslips were placed onto Mowiol, and cells were observed using an Axiovert 200M microscope (Carl Zeiss). To obtain semi-quantitative data regarding membrane tubulation, cells containing more than two tubular membrane structures longer than 20 μ m, as shown by the epifluorescent signal of each FKBP-BAR domain, were counted. Statistical significance was determined by Welch's t test.

For time-lapse recording, cells were placed on a microscope stage prewarmed to 37°C, and merged differential interference and fluorescence images were obtained using an A1R-MP confocal laser-scanning microscope (Nikon). Images were acquired every 16.0 sec, and movies play at a rate of 12.5 frames per second.

Immunoblotting

Cells were lysed in lysis buffer (20 mM HEPES-KOH [pH 7.4], 150 mM NaCl, 1 mM EDTA, and 1% NP-40) containing a protease inhibitor cocktail (Nacalai Tesque) for 20 min on ice. Cell lysates were centrifuged at 16,100 g for 15 min at 4°C in a microcentrifuge. Proteins

(30 μ g) were separated by SDS-PAGE and electroblotted onto an Immobilon-P transfer membrane (Millipore EMD). The membrane was blocked with 5% skimmed milk and sequentially incubated with the indicated primary and horseradish peroxidase-conjugated secondary antibodies. Signals were detected using a Chemi-Lumi One L or Chemi-Lumi One Super kit (Nacalai Tesque).

Flippase assay

Incorporation of NBD-phospholipids was analyzed by flow cytometry as described previously (Takatsu *et al.*, 2014). In brief, HeLa cells were detached from dishes in PBS containing 5 mM EDTA and harvested by centrifugation. Thereafter, cells (1×10^6 cells per sample) were washed and equilibrated at 15°C for 15 min in 500 μ L Hank's balanced salt solution (pH 7.4) containing 1 g/L glucose (HBSS-glucose). An equal volume of 2 μ M NBD-phospholipid prepared in HBSS-glucose was added to the cell suspension and incubated at 15°C. At each time point, 200 μ L of the cell suspension was collected and mixed with 200 μ L of ice-cold HBSS-glucose containing 5% fatty acid-free bovine serum albumin (BSA, Wako Pure Chemical) to extract NBD-lipids incorporated into the exoplasmic leaflet of the PM as well as unincorporated NBD-lipids. Next, 10,000 cells were analyzed on a FACSCalibur instrument (BD Biosciences) to measure the fluorescence of NBD-lipids that had translocated into the cytoplasmic leaflet of the PM. Mean fluorescence intensities per cell were calculated. Propidium iodide-positive cells (i.e., dead cells) were excluded from the analysis.

HeLa cells in 12-well plates (5×10^5 cells/well) were treated with rapamycin or nocodazole, or were exposed to hypotonic or hypertonic conditions in 500 μ L of 0.1 $\times$ HBSS-glucose or 500 μ L HBSS-glucose containing 200 mM sucrose, respectively, at 37°C for the indicated durations. Cells were equilibrated at 15°C for 15 min in the same buffer, and then treated with 500 μ L HBSS-glucose containing 2 μ M NBD-phospholipid at 15°C for 15 min. Thereafter, cells were detached from the plate and suspended in ice-cold PBS containing 2.5% fatty acid-free BSA, 5 mM EDTA, and 0.04% propidium iodide. Next, 10,000 cells were analyzed on a FACSCalibur instrument. Mean fluorescence intensities per cell were calculated. Propidium iodide-positive cells (i.e., dead cells) were excluded from the analysis.

Uptake of anti- β 1-integrin antibody

Cellular uptake of an anti- β 1-integrin antibody was assayed using a previously described method with some modifications (Nakai *et al.*, 2013, Shin & Nakayama, 2004,

Tanaka *et al.*, 2016). HeLa cells stably expressing ATP10A or ATP10A(E203Q) or *ATP10A*-knockout MDA-MB-231 cells were incubated with an anti- β 1-integrin antibody (Mab13) at 4°C for 1 h (HeLa cells) or 30 min (MDA-MB-231 cells), washed with ice-cold PBS, and incubated in medium lacking the antibody at 37°C for the indicated durations. Cells were washed with acidic solution (0.5% acetic acid and 0.5 M NaCl, pH 3.0) to remove residual antibodies from the PM prior to fixation. In case of MDA-MB-231 cells, fibronectin-coated cover glass was used to prevent detachment of cells from the cover glass upon temperature shift. Fixed cells were processed for immunofluorescence analysis as described above and imaged using an Axiovert 200 MAT microscope (Carl Zeiss). The fluorescence intensity of intracellular β 1-integrin was quantitated using MetaMorph software (Molecular Devices). Variance was assessed by a one-way ANOVA and comparisons were made by Tukey's post-hoc analysis.

RT-PCR

Total RNA was isolated from HeLa, MDA-MB-231, RPE-1, and HEK293T cells using an RNeasy mini kit (Qiagen). RT-PCR analysis was performed using a SuperScript III One-Step RT-PCR system (Invitrogen) and the following primer pairs: human CDC50A: sense, GAAAAAGAAAGGTATTGCTTGGTG, antisense, GTAATGTCAGCTGTATTACTACTG; human ATP10A: sense, CACAATGTTCGTGGGCCTCC, antisense, AAGGACACTGAAGCCACACG; human ATP8B1: sense, GTGGCCTCCACCAACCGGG, antisense, CACCTCTATTCCTCTGGTTTTCC; human ATP8B2: sense, GGGAGAGAGGCCTGAACCTG, antisense, GGAGTCCAGGATGGCCAGCAG.

Establishment of KO cell lines by the CRISPR/Cas9 system

To edit the *ATP10A* gene, we used the CRISPR/Cas9 system described previously (Katoh *et al.*, 2017, Tanaka *et al.*, 2016). Two single guide RNA (sgRNA) sequences (#1 and #2, Figure EV6A) targeting the human *ATP10A* gene were designed using the CRISPR Design Tool from the Zhang lab (<http://crispr.mit.edu/>). We used a donor plasmid of pDonor-tBFP-NLS-Neo (Addgene #80766) (Tanaka *et al.*, 2016) and PX459 (Addgene #48139). Two plasmids (plasmid containing *ATP10A* target sequences and the Cas9 gene, and a donor plasmid) were introduced into MDA-MB-231 cells by transfection using the X-tremeGENE9 DNA Transfection Reagent (Roche). Transfected cells were selected in medium containing G418 (1-4 mg/ml), and clones were isolated on the basis of expression of the reporter gene Tag-BFP. To confirm editing of *ATP10A*, genomic DNA was extracted from individual clones,

and subjected to PCR using KOD FX Neo DNA polymerase (TOYOBO). Three primer sets used to amplify *ATP10A* lacking the donor vector integration (S1, 5'-CGAGTGATGATAACCTAAGAGG-3', and AS1, 5'-GTTGATCTTGTGGTCGGAGC-3'), *ATP10A* with donor vector integrated in the forward orientation (donor vector-primer, 5'-GTTGTCCACGGTGCCCTCCATGTAC-3' and S1), and *ATP10A* with donor vector integrated in the reverse orientation (donor vector-primer and AS1). Among clones with donor vector integration in either orientation, the knockout was confirmed by direct sequencing of the amplified PCR product, *ATP10A* without donor vector integration, using a specific sequencing primer (S1 and/or donor vector-primer). Three clones (1-1, 2-1, and 2-6) carrying biallelic changes that resulted in donor vector integration in forward or reverse and frame-shifting indels were used in this study.

Author contributions

HWS, conceived the study and prepared the manuscript. NT, TN, and HT performed experiments. NT, HT, TN, KN, and HWS analyzed the data. All authors discussed the results and commented on the manuscript.

Conflict of interest

The authors declare that they have no conflict of interest.

Acknowledgments

We thank Hideki Shibata (Nagoya University) and Roger Tsien (University of California) for kindly providing plasmids as well as Zhiqiu Man for technical support. This work was supported by JSPS KAKENHI (Grant Numbers JP15H01320, JP16H00764, and JP17H03655 to H.-W.S.), the Takeda Science Foundation (to H.-W.S.). T.N. was supported by a JSPS Research Fellowship for Young Scientists.

Figure legends

Figure 1. Enhancement of PC-flippase activity at the PM upon expression of ATP10A triggers membrane tubulation by PM-recruited Δ N-BAR and F-BAR domains

HeLa cells stably expressing C-terminally HA-tagged ATP10A, ATP10A(E203Q), and ATP11A were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR), EGFP-FKBP- Δ N-BAR (Δ N-BAR), or mCherry-FKBP-F-BAR (F-BAR). Cells were treated with vehicle alone [Rapa(-)] or 200 nM rapamycin [Rapa(+)] for 15 min and fixed. Fixed cells were stained for an anti-HA primary antibody, followed by a Cy3-conjugated (A–C, G–I) or Alexa Fluor 488-conjugated (D–F) anti-rat secondary antibody. Panels b' and d' show enlarged images of the insets in b and d, respectively. Bars, 20 μ m. Bars in enlarged images, 2 μ m. (J–L) Cells containing membrane tubules were counted [420–672 cells (Δ N-BAR), 417–527 cells (F-BAR), and 422–805 cells (N-BAR) per sample]. Graphs display means $\pm$ SD of three independent experiments. **, $p < 0.01$; ***, $p < 0.005$.

Figure 2. Expression of ATP10A does not affect the integrity of the actin cytoskeleton or microtubules

HeLa cells stably expressing C-terminally HA-tagged ATP10A or ATP10A(E203Q) were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP- Δ N-BAR (Δ N-BAR). Cells were treated with 200 nM rapamycin for 15 min and fixed. Fixed cells were permeabilized and incubated with Alexa Fluor 555-conjugated phalloidin (A), or stained with an anti- β -tubulin primary antibody followed by an Alexa Fluor 555-conjugated anti-mouse secondary antibody (B). Panels a', and d'–i' show enlarged images of the insets in a, and d–i, respectively. Bars, 20 μ m. Bars in enlarged images, 2 μ m.

Figure 3. Disruption of microtubules reduced tubular structures caused by PM-recruited BAR-domains

(A, B, E) HeLa cells were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR), or EGFP-FKBP- Δ N-BAR (Δ N-BAR). (C, D, F, G) HeLa cells stably expressing HA-tagged ATP10A were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP- Δ N-BAR (Δ N-BAR), or mCherry-FKBP-F-BAR (F-BAR). (A–G) Transfected cells were pretreated with vehicle alone (Mock) or Nocodazole (Noz). The cells were further treated with vehicle alone or nocodazole

in the presence of rapamycin. Cells were fixed, permeabilized and stained with antibody against β -tubulin followed by Alexa Fluor 555– or Alexa Fluor 488–conjugated anti-mouse secondary antibody. Panels of b', c', e', e'', f', and f'' are enlarged images of insets in b, c, e, and f. Bars, 20 μ m. Bars in enlarged images, 2 μ m. (E–G) Cells containing membrane tubules were counted [429–492 cells (E), 397–479 cells (F), and 404–436 cells (G) in each sample]. Graphs display means $\pm$ SD from three independent experiments. *, $p < 0.05$; ****, $p < 0.001$. The experiments of (G) were performed together with Fig. 5F and thus the graph of Mock is equivalent to that of Fig. 5F.

Figure 4. Hypotonic treatment of HeLa cells prevents membrane tubulation induced by the PM-recruited N-BAR domain

HeLa cells were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR) or EGFP-FKBP- Δ N-BAR (Δ N-BAR). (A–D) Transfected cells were incubated in isotonic medium containing rapamycin (Mock) or exposed to hypotonic or hypertonic medium containing rapamycin. Cells were fixed, permeabilized, and incubated with Alexa Fluor 555-conjugated phalloidin. Panels b', c', e', and f' show enlarged images of the insets in b, c, e, and f, respectively. Bars, 20 μ m. Bars in enlarged images, 2 μ m. (E, F, G) Cells containing membrane tubules were counted [416–577 cells (N-BAR) and 402–467 cells (Δ N-BAR) per sample]. Graphs display means $\pm$ SD of three independent experiments. ***, $p < 0.005$.

Figure 5. Hypotonic treatment of ATP10A-expressing cells prevents membrane tubulation induced by PM-recruited Δ N-BAR and F-BAR domains

HeLa cells stably expressing C-terminally HA-tagged ATP10A were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP- Δ N-BAR (Δ N-BAR) (A, B, E) or mCherry-FKBP-F-BAR (F-BAR) (C, D, F). Transfected cells were incubated in isotonic medium containing rapamycin (Mock) or exposed to hypotonic or hypertonic medium containing rapamycin. Cells were fixed, permeabilized, and incubated with Alexa Fluor 555-conjugated (A, B) or Alexa Fluor 488-conjugated (C, D) phalloidin. Panels b', c', e', and f' show enlarged images of the insets in b, c, e, and f, respectively. Bars, 20 μ m. Bars in enlarged images, 2 μ m. (E, F) Cells containing membrane tubules were counted [400–452 cells (Δ N-BAR) and 404–436 cells (F-BAR) per sample]. Graphs display means $\pm$ SD of three independent experiments. **, $p < 0.01$; ***, $p < 0.005$.

Figure 6. Depletion of ATP10A abrogates membrane tubulation induced by Δ N-BAR and F-BAR domains in ATP10A-expressing cells

HeLa cells stably expressing HA-tagged ATP10A were transfected with a pool of siRNAs against LacZ (as a control) or ATP10A. After 96 h, cells were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR), EGFP-FKBP- Δ N-BAR (Δ N-BAR), or mCherry-FKBP-F-BAR (F-BAR). Cells were treated with vehicle alone [Rapa(-)] or 200 nM rapamycin [Rapa(+)] for 15 min and fixed. Fixed cells were stained with an anti-HA primary antibody followed by a Cy3-conjugated (A, E) or Alexa Fluor 488-conjugated (C) anti-rat secondary antibody. Bars, 20 μ m. Bars in enlarged images, 2 μ m. (B, D, F) Cells containing membrane tubules were counted [410–535 cells (Δ N-BAR), 389–464 cells (F-BAR), and 331–645 cells (N-BAR) per sample]. Graphs display means $\pm$ SD of three independent experiments. **, $p < 0.01$; ***, $p < 0.005$.

Figure 7. Expression of ATP10A increases the internalization rate of β 1-integrin

HeLa cells stably expressing C-terminally HA-tagged ATP10A, ATP10A(E203Q), or ATP11A were incubated with an anti- β 1-integrin antibody at 4°C for 1 h, washed with ice-cold PBS to remove unbound antibodies, and incubated at 37°C for the indicated durations to allow internalization of β 1-integrin. Cells were washed with acidic solution to remove residual antibodies on the PM prior to fixation. Fixed cells were permeabilized and incubated with a Cy3-conjugated anti-rat secondary antibody and Alexa Fluor 488-conjugated phalloidin. (A) Representative images are displayed. Insets show phalloidin staining. Bars, 20 μ m. (B) Fluorescence intensities of internalized β 1-integrin were quantitated using MetaMorph software. A total of 115–224 cells were analyzed per sample. Graphs display means $\pm$ SD of four independent experiments. *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.005$.

Figure 8. Schematic illustration of the sensing and/or generation of membrane curvature by BAR domains

(A) Penetration of the N-terminal amphipathic helix of the N-BAR domain has a wedging effect, leading to increased membrane curvature into the cytoplasm. The N-BAR domain subsequently senses this membrane curvature and triggers membrane tubulation by oligomerizing along the membrane (PDB: 4ATM, N-BAR domain of amphiphysin 1). (B) By contrast, the Δ N-BAR domain, which lacks the amphipathic helix, cannot generate membrane

curvature by itself, but can still sense membrane curvature. Thus, the Δ N-BAR domain can generate membrane tubulation following induction of membrane deformation by P4-ATPases.

EV Figure Legends

Figure EV1. Membrane tubulation is induced by recruitment of the N-BAR domain, but not of the Δ N-BAR or F-BAR domain, to the PM

(A) Schematic illustration of the CID system that allows acute recruitment of BAR domains to the PM following treatment with rapamycin. FP, fluorescent protein; FKBP, FK506-binding protein; FRB, FKBP-rapamycin-binding domain. (B–D) HeLa cells were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR), EGFP-FKBP- Δ N-BAR (Δ N-BAR), or mCherry-FKBP-F-BAR (F-BAR). After 24 h, cells were treated with vehicle alone [Rapa(–)] or 200 nM rapamycin [Rapa(+)] for 15 min, fixed, and observed using an epifluorescence microscope. Panels b', b'', d', and d'' show enlarged images of the insets in b and d. (E) HeLa cells were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP-N-BAR (N-BAR). After 24 h, cells were treated with 200 nM rapamycin for 15 min, fixed, and stained with an antibody against EEA1, Lamp-1, sorting nexin 1 (SNX1), or GM130 (markers of early endosomes, late endosomes/lysosomes, endosomes, and the Golgi complex, respectively) followed by an Alexa Fluor 555-conjugated anti-mouse secondary antibody.

Figure EV2. Flippase activity in ATP10A-expressing cells

(A) HeLa cells stably expressing HA-tagged P4-ATPases were lysed and subjected to SDS-PAGE and immunoblotting with an anti-HA or anti- β -tubulin antibody to determine the total level of the P4-ATPase protein. (B) HeLa cells stably expressing P4-ATPases were treated with vehicle alone [Rapa(–)] or 200 nM rapamycin [Rapa(+)] for 15 min. (C) HeLa cells stably expressing ATP10A were mock-transfected (Mock) or transiently co-transfected with expression vectors for Lyn-TagRFP-FRB (PM) and mCherry-FKBP, mCherry-FKBP- Δ N-BAR (Δ N-BAR), or mCherry-FKBP-N-BAR (N-BAR). After 24 h, cells were treated with 200 nM rapamycin. (D, E) HeLa cells stably expressing P4-ATPases were treated with vehicle alone (Mock), or 16.7 μ M of nocodazole or incubated in isotonic, hypotonic, or hypertonic medium. (B–E) Cells were then incubated with the indicated NBD-lipids at 15°C for 15 min. After extraction with fatty acid-free BSA, the residual fluorescence intensity associated with cells was determined by flow cytometry. The fold increase in NBD-lipid uptake relative to that

in vector-infected control cells (–) (B and D) or mCherry-FKBP-transfected cells (FKBP, (–)) (C) is shown. Graphs display means $\pm$ SD of three independent experiments.

Figure EV3. PM-recruited Δ N-BAR and F-BAR domains do not induce membrane tubulation in ATP10A(E203Q)-expressing cells

HeLa cells stably expressing C-terminally HA-tagged ATP10A(E203Q) were transiently co-transfected with expression vectors for Lyn-TagBFP2-FRB (PM) and EGFP-FKBP- Δ N-BAR (Δ N-BAR) (A, B) or mCherry-FKBP-F-BAR (F-BAR) (C, D). Transfected cells were incubated in isotonic medium containing rapamycin (Mock) or exposed to hypotonic or hypertonic medium containing rapamycin. Cells were fixed, permeabilized, and incubated with Alexa Fluor 555- or 488-conjugated phalloidin. Bars, 20 μ m. Bars in enlarged images, 2 μ m.

Figure EV4. Depletion of ATP10A in ATP10A-expressing cells

(A) RT-PCR was performed using total RNA isolated from the indicated cell lines. RNA was omitted in control reactions. (B) HeLa cells stably expressing HA-tagged ATP10A were treated with a pool of siRNAs targeting LacZ or ATP10A. After 120 h, cells were lysed and subjected to SDS-PAGE and immunoblotting with an anti-HA or anti- β -tubulin antibody. (–) indicates parental HeLa cells. (C) Cells treated with a pool of siRNAs targeting LacZ or ATP10A were incubated with NBD-PC at 15°C as described in the legend of Figure EV2. The fold increase in NBD-PC uptake relative to that in parental cells is shown. Graphs display means $\pm$ SD of three independent experiments.

Figure EV5. ATP1A1 localization in ATP10A-expressing cells

HeLa cells stably expressing C-terminally HA-tagged ATP10A, and ATP10A(E203Q) were fixed and stained for an anti-HA and anti-ATP1A1 primary antibodies, followed by a Cy3-conjugated anti-rat and Alexa488-conjugated anti-rabbit secondary antibodies. (A) Bars, 20 μ m. (B) Cells in which ATP1A1 localized to the plasma membrane (black), or to the plasma membrane and intracellular puncta (white) were counted: counts were normalized against the total number of counted cells (562-644 cells). Graphs display means of two independent experiments and error bars show minimum and maximum values.

Figure EV6. Internalization of β 1-integrin in ATP10A-knockout (KO) cells

ATP10A gene of MDA-MB-231 cells was edited by the CRISPR/Cas9 system. (A) Target sequences of *ATP10A* gene are shown. (B) In clone 1-1, clone 2-1, and clone 2-6, *ATP10A* carries biallelic modifications: insertion of a base and donor vector (reverse integration), deletion of 31 bases and insertion of donor vector (forward integration), and deletion of a base and insertion of donor vector (forward integration), respectively. (C) Parental MDA-MB-231 cells (-) and *ATP10A*-KO cell lines were incubated with an anti- β 1-integrin antibody at 4°C for 30 min, washed with ice-cold PBS to remove unbound antibodies, and incubated at 37°C for 30 min to allow internalization of β 1-integrin. Cells were washed with acidic solution to remove residual antibodies on the PM prior to fixation. Fixed cells were permeabilized and incubated with a Cy3-conjugated anti-rat secondary antibody. Fluorescence intensities of internalized β 1-integrin were quantitated using MetaMorph software. A total of 70–174 cells were analyzed per sample. Graphs display means $\pm$ SD of three independent experiments. (D) RT-PCR was performed using total RNA isolated from the indicated cell lines. RNA was omitted in control reactions.
