Evaluation of NO₂ sorption ability of cedar wood

(Laboratory of Sustainable Materials, RISH, Kyoto University)

Miyuki Nakagawa, Kenji Umemura, and Kozo Kanayama

Introduction

Nitrogen dioxide (NO₂) is a criteria air pollutant and affects human health, particularly the lungs and breathing passages. As representative materials for NO₂ removal, it is known that activated carbon, photocatalyst and terpenes from leaf oil have a high NO₂ sorption ability. However, use of these materials is limited by the problems of time-consuming production, decline in function depending on the weather and time, and waste liquid and residue disposal. Recently, it's known that Japanese cedar wood (*Cryptomeria Japonica*) has especially high NO₂ sorption ability compared with other wood species. Cedar wood is available itself as NO₂ removing material without any chemical or industrial treatment. Therefore, it has a great potential as a material for NO₂ removal. It is considered that NO₂ sorption ability of cedar wood is influenced by the structural features of tissues, moisture content and extractives. However, influences of each factor have not been evaluated in detail so far. We are trying to elucidate the influence on NO₂ sorption ability under various conditions focused on each factor by using a new system (Figure 1) for measuring NO₂ sorption volume developed by ourselves.

Experiment

In an incubator at 20 ± 1 °C, Japanese cedar wood having different form and drying condition were aerated with concentrated NO₂ (1000 ppb, flow velocity: 560 ml/min). NO₂ concentration before and after passing through the specimens were monitored with a NO_x monitoring devices. The amount of NO₂ sorption were calculated and compared among various specimens.

Results and discussion

When the NO₂ gas flowed over the surface of transverse section of specimen, the NO₂ sorption volume depended on the thickness of longitudinal direction and NO₂ sorption effect was high especially in the range of ca. 3 mm from the surface of transverse section. This range was almost same average length to the cedar tracheid. Also, NO₂ sorption volume depended on the interface area of the specimen which can contact with NO₂. These results show that the interface area which the structure of tracheid contributed was influenced to the NO₂ sorption ability. Furthermore, the average NO₂ sorption volume was the greatest in the specimen of natural drying and decreased as drying temperature was high. Because NO₂ sorption volume in extraction-treated specimen decreased to almost same values regardless of the drying temperature and it is reported that drying temperature is influenced to the amount of extractives in the wood by previous studies, the differences of amount of extractives by drying treatment seem to be influenced to the NO₂ sorption volume. We will examine the influence of moisture content as a next step.
