19

20 **ABSTRACT**

21 To improve our understanding of high copepod productivity in the estuarine turbidity maximum
22 (ETM) of the macrotidal Chikugo River estuary in southwestern Japan, we determined stable
23 carbon isotope ratios ($\delta^{13}\text{C}$) in the sympatric oligohaline copepods *Sinocalanus sinensis* and
24 *Pseudodiaptomus inopinus* from 2005 to 2006. Terrestrial-plant and phytoplankton detritus always
25 accumulated in the ETM (salinity 0.1–3), whereas outside the ETM phytoplankton dominated
26 especially in the warm season ($> 20^\circ\text{C}$). In contrast with the year-round concentration of *S. sinensis*
27 in the ETM, *P. inopinus* occurred widely along the upper estuary under phytoplankton-dominated
28 conditions. Terrestrial-plant detritus was characterized by relatively constant $\delta^{13}\text{C}$ (ca. -24‰),
29 suggesting that significant spatiotemporal variability in copepod $\delta^{13}\text{C}$ was attributable to the feeding
30 of copepods on phytoplankton and/or its detritus. Both copepods held relatively depleted $\delta^{13}\text{C}$
31 values in the ETM, reflecting $\delta^{13}\text{C}$ in freshwater/oligohaline phytoplankton ($< -24\text{‰}$). However,
32 relatively enriched $\delta^{13}\text{C}$ values ($> -24\text{‰}$) associated with meso/polyhaline phytoplankton
33 downstream from the ETM were found only in *P. inopinus*. Although the contribution of
34 terrestrial-plant detritus to copepod production remains to be determined, our results indicate that
35 both copepods selectively utilize freshwater/oligohaline phytoplankton and/or its detritus in the
36 ETM whereas only *P. inopinus* utilizes meso/polyhaline phytoplankton downstream from the ETM.

37

38 INTRODUCTION

39 The estuarine turbidity maximum (ETM) develops at low salinities in macrotidal estuaries through
40 the hydrodynamic function of tidal pumping and estuarine circulation (Allen *et al.*, 1980; Uncles *et*
41 *al.*, 2002). High densities of zooplankton are often associated with high concentrations of suspended
42 solids in the ETM (Castel and Veiga, 1990; Laprise and Dodson, 1994; North and Houde, 2003).
43 The ETM generally serves as a fish nursery, providing better feeding conditions to larval and
44 juvenile fish than other habitats (Dauvin and Dodson, 1990; Sirois and Dodson, 2000; Martino and
45 Houde, 2010). However, phytoplankton production is inhibited in the ETM, as light availability for
46 photosynthesis is severely reduced by the high turbidities that exist here (Irigoien and Castel, 1997;
47 Yokoyama *et al.*, 2012). Therefore, detrital food sources of allochthonous origin (e.g. freshwater
48 and marine phytoplankton and terrestrial plants) have been considered to subsidize high
49 zooplankton productivity in the ETM (Heinle and Flemer, 1975; Heinle *et al.*, 1977; Roman, 1984;
50 David *et al.*, 2006).

51 In Japan, the oligohaline copepod *Sinocalanus sinensis* occurs only in macrotidal estuaries
52 in the innermost part of the Ariake Sea (Hiromi and Ueda, 1987; Ohtsuka *et al.*, 1995; Ueda, 2005).
53 On the contrary, the copepod *Pseudodiaptomus inopinus* is widely distributed in brackish waters of
54 East Asia (Ohtsuka *et al.*, 1995; Sakaguchi *et al.*, 2011). Although both copepods coexist in the
55 macrotidal Chikugo River estuary, the largest estuary flowing into the Ariake Sea, *S. sinensis*
56 numerically dominates in and close to the ETM throughout the year except in the warm season
57 when *P. inopinus* outnumbers *S. sinensis* (Suzuki *et al.*, 2013). Given the vulnerability of eggs and
58 nauplii to washout from the estuary, large floods characteristic of the warm season are more
59 detrimental to the free-spawning species *S. sinensis* than to the egg-carrying species *P. inopinus*
60 (Suzuki *et al.*, 2012a). Besides their different reproduction strategies, differential food sources could
61 also explain the seasonal alternation of dominance between the two copepods. Terrestrial-plant and
62 phytoplankton detritus continuously accumulates in the ETM and therefore could ensure minimum
63 food for the two copepods throughout the year (Suzuki *et al.*, 2012b). In contrast, phytoplankton,

64 which proliferates outside the ETM in the warm season, could serve as nutritious food of limited
65 availability (Suzuki *et al.*, 2012b).

66 To test the hypothesis that the sympatric oligohaline copepods *S. sinensis* and *P. inopinus*
67 depend on differential food sources, we determined stable carbon isotope ratios ($\delta^{13}\text{C}$) in the two
68 copepods along the Chikugo River estuary monthly between 2005 and 2006. Photosynthetic
69 pigment concentrations and $\delta^{13}\text{C}$ in particulate organic carbon (POC) were also measured in
70 ambient water. Since $\delta^{13}\text{C}$ in animals reflect $\delta^{13}\text{C}$ in their diet (DeNiro and Epstein, 1978; Fry and
71 Sherr, 1984), spatiotemporal variability in copepod $\delta^{13}\text{C}$ was compared with that in POC $\delta^{13}\text{C}$.
72 Significant spatiotemporal variability in copepod $\delta^{13}\text{C}$ was attributed to the feeding of copepods on
73 phytoplankton and/or its detritus, as phytoplankton is characterized by spatiotemporally variable
74 $\delta^{13}\text{C}$ in contrast with relatively constant $\delta^{13}\text{C}$ in terrestrial plants (cf. Suzuki *et al.*, 2012b).
75 Differences in $\delta^{13}\text{C}$ between copepods and POC were used to evaluate selective feeding and/or
76 assimilation by copepods (cf. Del Giorgio and France, 1996). Dependence on differential food
77 sources is discussed between *S. sinensis* and *P. inopinus* in light of their respective patterns of
78 spatial occurrence relative to the ETM.

79

80 **METHOD**

81 **Study area**

82 The Chikugo River estuary is the largest estuary in the Ariake Sea in terms of both catchment area
83 (2860 km²) and freshwater discharge (annual median of daily averages: 60 m³ s⁻¹). The estuarine
84 environment is characterized by one of the largest tidal ranges in Japan (up to 5 m during spring
85 tides). The tidal reach is 4–8 m in depth and 300–1000 m in width at spring high tide, extending to
86 the Chikugo Weir 23 km upstream from the river mouth. Strong tidal currents completely mix the
87 water column during spring tides, whereas partial stratification occurs during neap tides (Suzuki *et al.*,
88 2007). The ETM is usually located 10–20 km upstream from the river mouth at spring high tide,
89 although it is transported back and forth over a 20-km range along the estuary with the semidiurnal

tidal cycle between high and low tides. Terrestrial-plant and phytoplankton detritus accumulates into the ETM throughout the year, whereas phytoplankton occurs abundantly outside the ETM during the warm season (Suzuki *et al.*, 2012b). Benthic microalgae are considered to be negligible compared with phytoplankton and terrestrial plants (Suzuki *et al.*, 2012b). Large floods occasionally affect the estuary and wash away the ETM especially in the warm season (Suzuki *et al.*, 2009). The spatiotemporal dynamics of the horizontal distribution of *S. sinensis* and *P. inopinus* along the estuary is published elsewhere (Suzuki *et al.*, 2012a). Moreover, the spatiotemporal dynamics of both concentration and origin of POC has been studied in detail relative to the fortnightly tidal cycle (Suzuki *et al.*, 2007), freshwater discharge levels (Suzuki *et al.*, 2009) and the seasonal succession (Suzuki *et al.*, 2012b).

Seven regular sampling stations (R1–R7; Fig. 1) were set up at intervals of 1.5–5.5 km along the lower reaches of the Chikugo River, located between the river mouth and the upper limit of the tidal reach (23 km upstream). Three regular sampling stations (E1–E3; Fig. 1) were set up along the main tidal channel of the river so that E1 was near the river mouth and E3 was at the edge of the tidal flat (9 km offshore). The freshwater discharge was continuously monitored 26 km upstream and the data were uploaded to the web site by the Chikugogawa River Office.

Field sampling

Monthly sampling was conducted at the ten regular sampling stations during the period March 2005 to December 2006. All sampling dates coincided approximately with spring tides. Sampling involved vertical hauls of a plankton net (45-cm mouth diameter, 100-cm long, 0.1-mm mesh aperture) from close to the bottom to the surface at $\sim 50 \text{ cm s}^{-1}$. Zooplankton was preserved in 5% formalin seawater solution for taxonomic analysis of copepods. The volume of water filtered was estimated using a flow meter (2030R, General Oceanics, USA) attached to the mouth of the plankton net. For $\delta^{13}\text{C}$ analysis of copepods, zooplankton was immediately frozen on dry ice. Frozen samples were transported to the laboratory and stored at -30°C until further analysis.

116 Temperature, salinity and turbidity were also measured from the bottom to the surface at depth
117 intervals of 1 or 2 m using environmental monitoring systems (6920 Sonde and 650 MDS Display,
118 YSI, USA; Compact-CTD, Alec Electronics, Japan). Turbidity was not measured in April and July
119 2005 and February 2006, due to mechanical faults of the turbidity sensor. Water samples were taken
120 from the surface with a bucket and prefiltered through a nylon screen (0.1-mm mesh aperture) to
121 remove zooplankton and plant debris before being packed in clean bottles. Plankton-net hauls and
122 environmental surveys were started at the uppermost station (R7) and finished at the lowermost
123 station (E3) within 4–5 h around high tide in the morning. To assess temporal changes in copepod
124 $\delta^{13}\text{C}$ in response to short-term environmental changes, a series of intensive sampling was conducted
125 once every 5 or 6 days from 8 June to 9 August 2005. This period of the year is considered to
126 represent the warm and wet season in southwestern Japan (Suzuki *et al.*, 2012b). Three extra
127 sampling stations (R2.5, R3.5 and R6.5; Fig. 1) were set to focus on the ETM and its surrounding
128 waters, whereas sampling was not conducted at stations far downstream from the ETM. Given
129 relatively weak mixing in the water column in summer, water samples were taken not only from the
130 surface but also from approximately 1 m above the bottom using a Van Dorn water sampler. The
131 other procedures for collecting biological and physical data were the same for those of the monthly
132 sampling.

133

134 **Laboratory analysis**

135 Water samples were filtered through Whatman GF/F filters that had been combusted at 400°C for 3h.
136 Depending on turbidity, water volume for filtration was adjusted (20–1000 ml). Duplicates were
137 made for each water sample to analyze photosynthetic pigments and $\delta^{13}\text{C}$ separately, although both
138 analyses were done once for each sample. Filter samples were kept frozen at -30°C until further
139 analysis. Half of the filters were extracted in the dark for 12 h with 90% acetone. Extracts were
140 measured for chlorophyll *a* and phaeopigment concentrations by the fluorometric method using a
141 calibrated Turner Designs TD 700 fluorometer (Japan Meteorological Agency, 1970). The

142 fluorescence of phaeopigments, an indicator of plant detritus, was quantified after acidification with
143 HCl. For $\delta^{13}\text{C}$ analysis of POC, the other half of the filters were dried at 60°C for 24 h and acidified
144 by fuming with HCl for 24 h to remove CaCO_3 . To neutralize the acid, samples were placed in a
145 desiccator with NaOH for more than 72 h and then redried. The processed samples were wrapped
146 separately in tin foil and kept dry in another desiccator.

147 To estimate density (ind. L^{-1}), adults and copepodids of *S. sinensis* and *P. inopinus* were
148 extracted from the formalin samples and identified under a stereo microscope ($\times 20\text{--}50$
149 magnification). For $\delta^{13}\text{C}$ analysis of copepods, the frozen zooplankton samples were thawed slowly
150 and identified to species under the stereo microscope during the period of thawing. Adults and
151 copepodids of *S. sinensis* and *P. inopinus* were pooled by species (~ 50 individuals) at each station
152 on each sampling date to obtain sufficient material for $\delta^{13}\text{C}$ analysis. Pooled samples were rinsed
153 with distilled water and wrapped separately in tin foil before being dried at 60°C for 24 h. Neither
154 acidification nor lipid extraction was conducted in zooplankton samples. All $\delta^{13}\text{C}$ values were
155 determined using a stable isotope ratio mass spectrometer (Delta S, Finnigan MAT, Germany) in the
156 continuous flow mode, equipped with an elemental analyzer (EA1108, Fisons Instrument, Italy).
157 Stable carbon isotope ratios are described as a per mil (‰) deviation from the international standard
158 (Peedee Belemnite) using the following equation: $\delta X = [(R_{\text{sample}}/R_{\text{standard}}) - 1] \times 1000$, where X and R
159 represent ^{13}C and $^{13}\text{C}/^{12}\text{C}$ ratio, respectively. To verify the accuracy of the analysis, DL-alanine was
160 used as a secondary standard. Standard deviations for the secondary standard were usually less than
161 0.1‰ for $\delta^{13}\text{C}$. Organic carbon and nitrogen concentrations in each sample were determined
162 simultaneously with $\delta^{13}\text{C}$ analysis using the elemental analyzer. The results were used to calculate
163 POC concentrations and organic carbon to nitrogen atomic ratios (hereafter, C:N ratios).

164 The C:N ratios in copepods were used as an indicator of lipid content, since depleted $\delta^{13}\text{C}$
165 values are frequently associated with a high lipid content (Matthews and Mazumder, 2005; Smyntek
166 *et al.*, 2007). In contrast, enriched $\delta^{13}\text{C}$ values are sometimes attributable to a high carbonate
167 content and therefore acidification is recommended by some researchers (Jacob *et al.*, 2005;

168 Carabel *et al.*, 2006). However, the effect of carbonate on copepod $\delta^{13}\text{C}$ was not considered in the
169 present study, because carbonate content was considered to be minor in copepods and acidification
170 might increase inter-individual variation in $\delta^{13}\text{C}$ (cf. Bunn *et al.*, 1995). Although each sampling
171 station was represented by a single pair of POC and copepod samples per sampling date, this
172 laborsaving procedure is considered to be accurate enough to survey spatial variation in POC and
173 copepods along the estuary (cf. Suzuki *et al.*, 2012b).

174

175 **Data analysis**

176 Temperature, salinity and turbidity were averaged through the water column. Average temperature
177 was used to divide a year into cold ($< 20^{\circ}\text{C}$) and warm ($> 20^{\circ}\text{C}$) seasons. Average salinity was used
178 as an indicator of distinctive water masses, because the distribution of water masses changes
179 considerably along the estuary in response to the fortnightly tidal cycle as well as freshwater
180 discharge levels (Suzuki *et al.*, 2007, 2009). Based on the result of the present study, four water
181 masses were distinguished empirically by salinity ranges of < 0.1 , $0.1\text{--}3$, $3\text{--}20$, > 20 (without
182 statistics). To assess the spatiotemporal variability in environmental conditions, effects of salinity
183 and temperature on environmental parameters (e.g. turbidity, POC and chlorophyll *a*) were analyzed
184 by two-way repeated-measures analysis of variance (hereafter, two-way ANOVA) on the software
185 JMP Ver. 5 (SAS Institute Inc., USA). In the intensive sampling campaign, surface and bottom
186 values were averaged to determine concentrations of chlorophyll *a*, phaeopigments and POC, and
187 $\delta^{13}\text{C}$ in POC. Although all environmental parameters (absolute values for $\delta^{13}\text{C}$) were
188 logarithmically transformed to assure preconditions for two-way ANOVA, normality and/or
189 homogeneity of variance were not always satisfied even after the logarithmic transformation. It
190 follows that provisional results might be included in the two-way ANOVA tests.

191 To evaluate selective feeding and/or assimilation by copepods (cf. Del Giorgio and France,
192 1996), differences in $\delta^{13}\text{C}$ between copepods and POC were calculated by subtracting POC $\delta^{13}\text{C}$
193 from copepod $\delta^{13}\text{C}$ at each station on each sampling date (hereafter, $\Delta\delta^{13}\text{C}$). The significance of

194 correlations of copepod parameters ($\delta^{13}\text{C}$, C:N ratios and $\Delta\delta^{13}\text{C}$) with environmental parameters
195 (e.g. salinity, turbidity and POC) was tested by Spearman's correlation coefficient. Kruskal-Wallis
196 test was used to compare $\Delta\delta^{13}\text{C}$ values among salinity ranges (< 0.1 , $0.1\text{--}3$, > 3). The significance
197 level of the statistical tests was set at 5%.

198

199 **RESULTS**

200 **Year-round environmental conditions**

201 Environmental conditions varied markedly with salinity along the estuary throughout the year.
202 Turbidity usually exceeded 200 NTU at salinities $0.1\text{--}10$ with highest values (up to 1000 NTU) at
203 salinity $0.1\text{--}3$ (Fig. 2A, Table I). The scatter pattern of POC concentrations differed from that of
204 chlorophyll *a*, but corresponded closely with that of phaeopigments (Fig. 2B–D). Concentrations of
205 POC and phaeopigments were usually higher at salinities $0.1\text{--}3$ under high turbidity conditions
206 (Table I). Significant differences among salinity ranges combined with no clear seasonal change
207 were found in turbidity, POC and phaeopigments (two-way ANOVA, $P < 0.05$, Table II). On the
208 contrary, higher chlorophyll *a* concentrations were found at salinities < 0.1 and > 20 under low
209 turbidity conditions (Table I). Chlorophyll *a* reached high concentrations mainly in the warm season
210 (Table I). However, a significant interaction between salinity and temperature (two-way ANOVA, P
211 < 0.05 , Table II) obscured their respective effects on chlorophyll *a* concentrations.

212 Low POC:chlorophyll *a* ratios (< 100) occurred only at salinities < 0.1 and > 20 in the
213 warm season, indicating the dominance of phytoplankton in POC (Fig. 2E). The $\delta^{13}\text{C}$ values in POC
214 were depleted ($< -25\text{‰}$) at salinities < 0.1 and enriched ($> -23\text{‰}$) at salinities > 20 in the warm
215 season (Fig. 2F). This was in contrast with relatively constant $\delta^{13}\text{C}$ values ($-25\text{--}-23\text{‰}$) in POC at
216 salinities $0.1\text{--}20$ throughout the year (Table I). However, effects of salinity and temperature were
217 not statistically confirmed in POC:chlorophyll *a* ratios and POC $\delta^{13}\text{C}$ values because of significant
218 interactions between salinity and temperature (two-way ANOVA, $P < 0.05$, Table II). Exceptionally
219 low salinities were observed through the tidal reach under recurring flood conditions in July 2006

220 (cf. Suzuki *et al.*, 2012b). Lowest concentrations of POC, chlorophyll *a* and phaeopigments were
221 accompanied by high POC:chlorophyll *a* ratios (> 1000) and constant $\delta^{13}\text{C}$ values in POC (-24.5‰)
222 in the flood period.

223

224 **Year-round comparisons between *S. sinensis* and *P. inopinus***

225 Irrespective of the season, *S. sinensis* exhibited a unimodal pattern of distribution along the
226 estuarine salinity gradient, exceeding 1 ind. L^{-1} at salinities 0.1–10 with highest densities close to
227 salinity 1 (Fig. 3A). The $\delta^{13}\text{C}$ values in *S. sinensis* were distributed over -30 – -25‰ and slightly
228 more enriched at higher salinities (Spearman's correlation coefficient: $r_s = 0.45$, $P < 0.05$). The
229 majority of C:N ratios in *S. sinensis* ranged from 4.5 to 5.5, although higher C:N ratios occurred at
230 higher salinities ($r_s = 0.38$, $P < 0.05$). In contrast to *S. sinensis*, *P. inopinus* exhibited a clear
231 seasonal change in density, exceeding 1 ind. L^{-1} almost only in the warm season ($> 20^\circ\text{C}$; Fig. 3B).
232 Such high densities of *P. inopinus* were observed over a relatively wide salinity range (0.1–20). The
233 $\delta^{13}\text{C}$ values in *P. inopinus* were strongly correlated with salinity ($r_s = 0.71$, $P < 0.05$): -30 – -27‰ at
234 lower salinities and -26 – -23‰ at higher salinities. The C:N ratios in *P. inopinus* ranged from 4.5 to
235 5.5 without a clear relationship with salinity ($r_s = -0.08$, $P > 0.05$). No seasonal change was evident
236 in $\delta^{13}\text{C}$ values or C:N ratios in both *S. sinensis* and *P. inopinus*.

237 In *S. sinensis*, $\Delta\delta^{13}\text{C}$ values were scattered over -7 – -1‰ and weakly correlated with
238 salinity ($r_s = 0.29$, $P < 0.05$; Fig. 4A). Lower $\Delta\delta^{13}\text{C}$ values, by definition, represent larger
239 differences in $\delta^{13}\text{C}$ between copepods and POC. Although $\Delta\delta^{13}\text{C}$ values were significantly lower at
240 higher phaeopigment concentrations ($r_s = -0.33$, $P < 0.05$), they were not correlated with any other
241 environmental parameters considered in *S. sinensis* (Table III). *Pseudodiaptomus inopinus* held
242 significantly lower $\Delta\delta^{13}\text{C}$ values (-7 – -1‰) at salinities 0.1–3 compared with higher $\Delta\delta^{13}\text{C}$ values
243 (-4 – -1‰) outside this salinity range (Kruskal-Wallis test, $P < 0.05$; Fig. 4B). The $\Delta\delta^{13}\text{C}$ differences
244 among the salinity ranges were less obvious in the cold season ($< 20^\circ\text{C}$) when *P. inopinus* seldom
245 occurred at salinities < 0.1 . In contrast with *P. inopinus*, such $\Delta\delta^{13}\text{C}$ differences among the salinity

246 ranges were not observed in *S. sinensis* (Kruskal-Wallis test, $P > 0.05$). Whereas *P. inopinus* held
247 significantly lower $\Delta\delta^{13}\text{C}$ values at higher turbidities and higher concentrations of POC and
248 phaeopigments throughout the year ($r_s = -0.28, -0.61$ and -0.60 , respectively; $P < 0.05$; Table III),
249 this species held higher and less variable $\Delta\delta^{13}\text{C}$ values at lower POC:chlorophyll *a* ratios in the
250 warm season ($> 20^\circ\text{C}$).

251

252 **Responses to short-term environmental changes**

253 In summer 2005, the daily freshwater discharge was small ($< 50 \text{ m}^3 \text{ s}^{-1}$) in June before causing a
254 large flood event (up to $1768 \text{ m}^3 \text{ s}^{-1}$) in early July (Fig. 5A). The discharge gradually settled down to
255 the previous level by late July. Before the flood, chlorophyll *a* concentrations were highest close to
256 the upper limit of the tidal reach in contrast with high phaeopigment concentrations observed
257 slightly more downstream (Fig. 5B). Both chlorophyll *a* and phaeopigment concentrations
258 decreased drastically during the flood, whereas after the flood they regained similar spatial patterns
259 to those observed before the flood. The $\delta^{13}\text{C}$ values in POC remained relatively enriched ($> -26\text{‰}$)
260 at all stations before and during the flood, with the exception of the most upstream station on 24
261 June (Fig. 5C). After the flood, more depleted $\delta^{13}\text{C}$ values in POC ($< -26\text{‰}$) occurred especially at
262 upstream stations. The $\delta^{13}\text{C}$ values in both *S. sinensis* and *P. inopinus* apparently reflected the
263 spatiotemporal variability in POC $\delta^{13}\text{C}$: relatively enriched at all stations before the flood and
264 relatively depleted at upstream stations after the flood.

265 Different responses to flood-induced environmental changes between *S. sinensis* and *P.*
266 *inopinus* were revealed when the data were analyzed in relation to salinity. Except during the flood,
267 high chlorophyll *a* concentrations ($> 20 \mu\text{g L}^{-1}$), combined with low POC:chlorophyll *a* ratios ($<$
268 100), were observed close to salinity 0.1 , in contrast with high phaeopigment concentrations (> 20
269 $\mu\text{g L}^{-1}$) observed at salinities $0.1\text{--}3$ (Fig. 6A–C). The $\delta^{13}\text{C}$ values in POC were relatively enriched
270 ($> -26\text{‰}$) over the whole salinity range before the flood, whereas after the flood they were
271 drastically depleted ($< -26\text{‰}$) at salinities < 0.1 (Fig. 6D). During the flood, the whole sampling

area was dominated by fresh water characterized by low concentrations of chlorophyll *a* and phaeopigments, high POC:chlorophyll *a* ratios and constant POC $\delta^{13}\text{C}$ values (ca. -24‰). Irrespective of salinity, *S. sinensis* showed completely different $\delta^{13}\text{C}$ values before and after the flood ($> -27\text{‰}$ and $< -27\text{‰}$, respectively; Fig. 6E). Although *P. inopinus* also showed relatively enriched $\delta^{13}\text{C}$ values ($> -27\text{‰}$) over the whole salinity range before the flood, this species exhibited a strong correlation of $\delta^{13}\text{C}$ with salinity ($r_s = 0.84$, $P < 0.05$) after the flood (Fig. 6F). This strong correlation was primarily attributable to $\delta^{13}\text{C}$ values in *P. inopinus* observed outside the salinity range of 0.1–3.

280

281 **DISCUSSION**

Food sources for the sympatric oligohaline copepods *S. sinensis* and *P. inopinus* were estimated from detailed comparisons of spatiotemporal variability in $\delta^{13}\text{C}$ between copepods and POC. Both copepods selectively utilize freshwater/oligohaline phytoplankton and/or its detritus in the ETM, whereas only *P. inopinus* utilizes meso/polyhaline phytoplankton downstream from the ETM. To estimate food sources accurately, preconditions for the interpretation of $\delta^{13}\text{C}$ data are discussed first. Dependence on differential food sources is discussed between the two copepods in light of their respective patterns of spatial occurrence relative to the ETM.

289

290 **Preconditions for interpretation**

Spatial heterogeneity in environmental conditions along the salinity gradient of the Chikugo River estuary was clearly demonstrated in the present study as compared with previous studies (Suzuki *et al.*, 2007, 2009, 2012b). High turbidities, accompanied by high concentrations of POC and phaeopigments, always occurred at salinities 0.1–3. Therefore we define the ETM by the salinity range of 0.1–3. Up- and downstream from the ETM, the dominance of living phytoplankton was often indicated by high chlorophyll *a* concentrations and low POC:chlorophyll *a* ratios especially in the warm season. Phytoplankton production is probably facilitated in relatively transparent and

298 warm waters (Suzuki *et al.*, 2012b; Yokoyama *et al.*, 2012). On the contrary, terrestrial-plant and
299 phytoplankton detritus is likely to accumulate in the ETM throughout the year (Suzuki *et al.*,
300 2012b). Generally, such spatiotemporal changes in environmental conditions are considered
301 common in macrotidal estuaries where the ETM develops markedly (Irigoien and Castel, 1997;
302 Lemaire *et al.*, 2000; Modéran *et al.*, 2010; Savoye *et al.*, 2012).

303 To interpret spatiotemporal variability in stable isotope ratios in animals, it is important to
304 determine both fractionation and turnover of stable isotope ratios in animals through laboratory
305 experiments (Gannes *et al.*, 1997). Since such experiments were not conducted in the present study,
306 the fractionation and turnover of $\delta^{13}\text{C}$ in copepods are estimated from our field observations and the
307 literature. The fractionation of $\delta^{13}\text{C}$ is generally small between animals and their diet (i.e. $\pm 1\text{‰}$;
308 DeNiro and Epstein, 1978; Fry and Sherr, 1984), whereas it is often affected by the lipid content of
309 animals due to distinctly depleted $\delta^{13}\text{C}$ values in lipids (DeNiro and Epstein, 1977). Differences in
310 lipid content can be responsible for variability in $\delta^{13}\text{C}$ within a copepod species (Matthews and
311 Mazumder, 2005; Smyntek *et al.*, 2007). However, relatively low and invariable C:N ratios indicate
312 that lipid content is unlikely to have affected copepod $\delta^{13}\text{C}$ values in the present study. Therefore it
313 is possible to estimate the fractionation of $\delta^{13}\text{C}$ between copepods and their food sources at $\pm 1\text{‰}$
314 (DeNiro and Epstein, 1978; Fry and Sherr, 1984). Although food quality can be another
315 complicating factor in isotopic fractionation, laboratory experiments are necessary to obtain the
316 relevant information (cf. Aberle and Malzahn, 2007).

317 In response to flood-induced environmental changes in summer 2005, copepod $\delta^{13}\text{C}$ values
318 varied drastically between late June and late July (or early August), although new cohorts could
319 have replaced old ones to some extent (Suzuki *et al.*, 2012a). This indicates that copepod $\delta^{13}\text{C}$
320 values possibly reflect environmental changes within several weeks in the warm season. Based on
321 high growth rates reported in *Sinocalanus tenellus* (Kimoto *et al.*, 1986) and *Pseudodiaptomus*
322 *marinus* (Uye *et al.*, 1983) at 20°C, the $\delta^{13}\text{C}$ values in *S. sinensis* and *P. inopinus* should converge
323 on a $\delta^{13}\text{C}$ value in new diet within one week after a diet switch (cf. Klein Breteler *et al.*, 2002).

Such quick turnover rates of $\delta^{13}\text{C}$ in copepods would justify our simple method in which copepod $\delta^{13}\text{C}$ values were compared with POC $\delta^{13}\text{C}$ values without taking account of time lag. At lower temperatures, turnover rates of $\delta^{13}\text{C}$ in copepods may be slower due to lower growth and metabolic rates (cf. Tamelander *et al.*, 2006). Nevertheless, our overlooking of time lag is unlikely to have affected the results considerably, because POC $\delta^{13}\text{C}$ values were less variable in the cold season. Our monthly comparisons of copepod $\delta^{13}\text{C}$ with POC $\delta^{13}\text{C}$ would therefore provide reliable information about food sources for copepods throughout the year.

Food sources for *S. sinensis* and *P. inopinus*

In the ETM, *S. sinensis* and *P. inopinus* are considered to prefer freshwater/oligohaline phytoplankton and its detritus over terrestrial-plant detritus. The $\delta^{13}\text{C}$ values in terrestrial-plant detritus are relatively constant (ca. -24‰), as is well represented in POC $\delta^{13}\text{C}$ values during floods (Suzuki *et al.*, 2012b). Consequently, more depleted $\delta^{13}\text{C}$ values observed in copepods throughout the year should be attributable to freshwater/oligohaline phytoplankton. This idea is supported by temporal changes in copepod $\delta^{13}\text{C}$ values observed during the intensive sampling campaign. As the $\delta^{13}\text{C}$ values in freshwater/oligohaline phytoplankton became depleted after the flood, *S. sinensis* and *P. inopinus* gradually displayed depleted $\delta^{13}\text{C}$ values in the ETM, probably feeding on freshwater/oligohaline phytoplankton and its detritus. Generally, feeding preferences of copepods for phytoplankton and its detritus are considered common in many estuaries (Tackx *et al.*, 2003; Martineau *et al.*, 2004; Hoffman *et al.*, 2008). Copepods feed selectively on more nutritious food sources (Cowles *et al.*, 1988; DeMott, 1995; Tackx *et al.*, 1995), although selection processes may differ among species (Richman *et al.*, 1977; Irigoien *et al.*, 1996). Feeding on terrestrial-plant detritus is nevertheless attractive especially in the cold season when phytoplankton is scarce (Suzuki *et al.*, 2012b). Specifically, *S. sinensis* might utilize terrestrial-plant detritus to maintain its year-round large biomass in the ETM (Suzuki *et al.*, 2012a, 2013).

The stenohaline copepod *S. sinensis* always concentrated close to salinity 1 in the ETM,

350 where terrestrial-plant and phytoplankton detritus accumulated throughout the year (Suzuki *et al.*,
351 2012b). The $\Delta\delta^{13}\text{C}$ values in *S. sinensis* were usually distant from the estimated fractionation of
352 $\delta^{13}\text{C}$ between copepods and their food source (i.e. $\pm 1\text{‰}$). Given that larger differences in $\delta^{13}\text{C}$
353 between copepods and POC are associated with greater selectivity in feeding and/or assimilation by
354 copepods (cf. Del Giorgio and France, 1996), *S. sinensis* is considered to be highly selective about
355 its food source in favor of freshwater/oligohaline phytoplankton and its detritus. Moreover, the total
356 absence of relatively enriched $\delta^{13}\text{C}$ values ($> -24\text{‰}$) in *S. sinensis* indicates little or no dependence
357 on meso/polyhaline phytoplankton. We argue that the feeding strategy of *S. sinensis* is closely
358 linked to the accumulation of detritus in the ETM, which constitutes an irreplaceable habitat for *S.*
359 *sinensis* compared with other estuarine environments (Suzuki *et al.*, 2012a, 2013). In contrast, the
360 less stenohaline copepod *P. inopinus* occurred not only in the ETM but also in its surrounding
361 waters. Up- and downstream from the ETM, this species often exhibited $\Delta\delta^{13}\text{C}$ values of $\pm 1\text{‰}$,
362 clearly reflecting $\delta^{13}\text{C}$ values in phytoplankton. The most enriched $\delta^{13}\text{C}$ values in *P. inopinus* were
363 comparable with the average $\delta^{13}\text{C}$ value in the herbivorous copepod *Acartia omorii* in the lower
364 estuary (Uchima, 1988; Suzuki *et al.*, 2008). These findings suggest that *P. inopinus* feeds
365 unselectively on living phytoplankton outside the ETM whereas in the ETM *P. inopinus* is selective
366 about its food source like *S. sinensis*.

367

368 CONCLUSIONS

369 The present study demonstrates that freshwater/oligohaline phytoplankton and its detritus constitute
370 the main food sources for both *S. sinensis* and *P. inopinus* in the ETM, although the possible
371 contribution of terrestrial-plant detritus to their production remains to be determined. The less
372 stenohaline copepod *P. inopinus* utilizes relatively diverse food sources depending on
373 environmental conditions along the estuarine salinity gradient. Feeding on living phytoplankton
374 outside the ETM, combined with an egg-carrying strategy in reproduction, could explain the large
375 biomass of *P. inopinus* during the warm season (Suzuki *et al.*, 2012a). In contrast, the stenohaline

376 copepod *S. sinensis* is restricted within the ETM and unlikely to utilize meso/polyhaline
377 phytoplankton. To estimate the relative contribution of phytoplankton and terrestrial plants to
378 copepod production, additional tracers will be useful (e.g. fatty acid composition, ^{13}C and ^{15}N
379 labeling). It is also a challenge to reveal biological mechanisms of *S. sinensis* underlying its
380 year-round large biomass in the ETM (e.g. ecological and physiological tolerance for high
381 turbidities). As the production of larval and juvenile fish is entirely supported by *S. sinensis* and *P.*
382 *inopinus* in the Chikugo River estuary (Hibino *et al.*, 1999; Suzuki *et al.*, 2008, submitted), further
383 investigations on the two copepods will improve our understanding of the productive food web in
384 the ETM.

386 **FUNDING**

387 The present study was partially supported by Grants-in-Aid from the Ministry of Education, Culture,
388 Sports, Science and Technology, Japan.

389

390 **ACKNOWLEDGEMENTS**

391 We wish to express our gratitude to Mr S. Koga of Okinohata Fisheries Cooperative Association
392 and Mr T. Tsukamoto of Shimochikugo Fisheries Cooperative Association for their assistance with
393 field sampling. We are also grateful to Fukuoka Fisheries & Marine Technology Research Center.
394 Dr A. Kasai of the Laboratory of Fisheries and Environmental Oceanography, Kyoto University,
395 provided us with technical advice concerning stable carbon isotope ratios. Dr J. Shoji of Takehara
396 Fisheries Research Laboratory, Hiroshima University, Dr T. Wada of Fukushima Prefectural
397 Fisheries Experimental Station, Dr R. Sugimoto of the Research Center for Marine Bioresources,
398 Fukui Prefectural University, and former students in our laboratory helped with field sampling. Mr.
399 J. Grigor kindly reviewed the manuscript in terms of English grammar. Photosynthetic pigments
400 and stable carbon isotope ratios were analyzed at the Laboratory of Marine Environmental
401 Microbiology and the Center for Ecological Research, Kyoto University, respectively.

555 *calculated for each combination of salinity ($S < 0.1$, $0.1-3$, $3-20$, >20) and temperature ($T < 20^\circ\text{C}$,*
556 *$>20^\circ\text{C}$) ranges.*

557

558 **Table II:** *Summary of the two-way repeated-measures analysis of variance of environmental*
559 *parameters observed in the Chikugo River estuary from March 2005 to December 2006. Four*
560 *salinity ranges ($S < 0.1$, $0.1-3$, $3-20$, >20) and two temperature ranges ($T < 20^\circ\text{C}$, $>20^\circ\text{C}$) were*
561 *set to assess the spatiotemporal variability of the environmental parameters.*

562

563 **Table III:** *Spearman's correlation coefficients of $\Delta\delta^{13}\text{C}$ in *S. sinensis* and *P. inopinus* relative to*
564 *salinity, turbidity, particulate organic carbon (POC), chlorophyll a (Chl. a), phaeopigments*
565 *(Pheo.) and POC:Chl. a ratios in the Chikugo River estuary from March 2005 to December 2006.*
566 *$\Delta\delta^{13}\text{C}$ values were calculated by subtracting $\delta^{13}\text{C}$ in POC from $\delta^{13}\text{C}$ in copepods at each station*
567 *on each sampling date. Significant coefficients are indicated by asterisks.*

568

569 **Fig. 1.** *Sampling stations along the Chikugo River estuary on Kyushu Island in southwestern Japan.*
570 *Black and white circles represent our regular and extra sampling stations, respectively. The*
571 *Chikugo Weir is represented by a black rectangle.*

572

573 **Fig. 2.** *Environmental conditions observed along the salinity gradient of the Chikugo River estuary*
574 *from March 2005 to December 2006. Turbidity (A), particulate organic carbon (POC)*
575 *concentrations (B), chlorophyll a concentrations (C), phaeopigment concentrations (D),*
576 *POC:chlorophyll a ratios (E) and stable carbon isotope ratios ($\delta^{13}\text{C}$) in POC (F) are shown.*

Crosses and exes represent values observed in the cold ($< 20^{\circ}\text{C}$) and warm ($> 20^{\circ}\text{C}$) seasons, respectively.

Fig. 3. Adult/copepodid density, stable carbon isotope ratios ($\delta^{13}\text{C}$) and carbon to nitrogen atomic ratios (C:N) observed in *S. sinensis* (A) and *P. inopinus* (B) along the salinity gradient of the Chikugo River estuary from March 2005 to December 2006. Black and white symbols represent values observed in the cold ($< 20^{\circ}\text{C}$) and warm ($> 20^{\circ}\text{C}$) seasons, respectively. Spearman's correlation coefficients are indicated by r_s .

Fig. 4. Differences in $\delta^{13}\text{C}$ ($\Delta\delta^{13}\text{C}$) between copepods and particulate organic carbon (POC) observed in *S. sinensis* (A) and *P. inopinus* (B) in the Chikugo River estuary from March 2005 to December 2006. $\Delta\delta^{13}\text{C}$ values are shown in relation to salinity, phaeopigment concentrations and POC:chlorophyll *a* ratios. See Fig. 3 for details.

Fig. 5. Temporal changes in freshwater discharge (A), in horizontal distributions of chlorophyll *a* and phaeopigments (B), and in interrelations of stable carbon isotope ratios ($\delta^{13}\text{C}$) among particulate organic carbon (POC), *S. sinensis* and *P. inopinus* (C) observed along the Chikugo River estuary in summer 2005. Arrows indicate sampling dates.

Fig. 6. Environmental conditions and stable carbon isotope ratios ($\delta^{13}\text{C}$) observed along the salinity gradient of the Chikugo River estuary in summer 2005. Chlorophyll *a* concentrations (A), phaeopigment concentrations (B), POC:chlorophyll *a* ratios (C), $\delta^{13}\text{C}$ in POC (D), $\delta^{13}\text{C}$ in *S. sinensis* (E) and $\delta^{13}\text{C}$ in *P. inopinus* (F) are shown. Black, white and grey symbols represent values observed before, during and after the flood of early July, respectively.

Table I: Average of turbidity, particulate organic carbon (POC), chlorophyll *a* (Chl. *a*), phaeopigments (Phaeo.), POC:Chl. *a* ratios, and stable carbon isotope ratios ($\delta^{13}\text{C}$) observed in the Chikugo River estuary from March 2005 to December 2006. The average values were calculated for each combination of salinity ($S < 0.1$, $0.1-3$, $3-20$, >20) and temperature ($T < 20^\circ\text{C}$, $>20^\circ\text{C}$) ranges.

	Turbidity (NTU)		POC (mg L ⁻¹)		Chl. <i>a</i> (µg L ⁻¹)		Phaeo. (µg L ⁻¹)		POC:Chl. <i>a</i>		$\delta^{13}\text{C}$ (‰)	
	T<20°C	T>20°C	T<20°C	T>20°C	T<20°C	T>20°C	T<20°C	T>20°C	T<20°C	T>20°C	T<20°C	T>20°C
S<0.1	62	57	1.8	1.4	6.6	13.4	3.7	5.3	357	442	-25.3	-26.1
0.1<S<3	413	461	10.1	7.3	8.8	17.8	22.5	20.0	1726	693	-24.4	-24.0
3<S<20	132	228	3.1	3.2	4.5	7.0	7.4	9.4	1094	845	-24.1	-23.3

6

7 **Table II:** Summary of the two-way repeated-measures analysis of variance of environmental
8 parameters observed in the Chikugo River estuary from March 2005 to December 2006. Four
9 salinity ranges ($S < 0.1$, $0.1-3$, $3-20$, >20) and two temperature ranges ($T < 20^{\circ}\text{C}$, $>20^{\circ}\text{C}$) were set
10 to assess the spatiotemporal variability of the environmental parameters.

	Turbidity ($df_E = 181$)	POC ($df_E = 210$)	Chl. <i>a</i> ($df_E = 210$)	Phaeo. ($df_E = 210$)	POC:Chl. <i>a</i> ($df_E = 210$)	$\delta^{13}\text{C}$ ($df_E = 209$)
S ($df_S = 3$)	$F = 48.7$ $P < 0.01$	$F = 70.8$ $P < 0.01$	$F = 7.3$ $P < 0.01$	$F = 37.0$ $P < 0.01$	$F = 20.8$ $P < 0.01$	$F = 67.0$ $P < 0.01$
T ($df_T = 1$)	$F = 1.2$ $P = 0.27$	$F = 0.2$ $P = 0.62$	$F = 40.3$ $P < 0.01$	$F = 0.0$ $P = 0.89$	$F = 38.4$ $P < 0.01$	$F = 5.4$ $P = 0.02$
S×T ($df_{S \times T} = 3$)	$F = 1.9$ $P = 0.13$	$F = 2.2$ $P = 0.09$	$F = 7.1$ $P < 0.01$	$F = 1.8$ $P = 0.15$	$F = 2.7$ $P = 0.05$	$F = 6.7$ $P < 0.01$

11 The F and P values were calculated after logarithmic transformation for turbidity, particulate
12 organic carbon (POC), chlorophyll *a* (Chl. *a*), phaeopigments (Phaeo.), POC:Chl. *a* ratios and
13 stable carbon isotope ratios ($\delta^{13}\text{C}$). Degrees of freedom for salinity (df_S), temperature (df_T),
14 interaction between them ($df_{S \times T}$) and error (df_E) are given in parentheses. Boldface type indicates
15 statistically significant values.

16

17 **Table III:** Spearman's correlation coefficients of $\Delta\delta^{13}\text{C}$ in *S. sinensis* and *P. inopinus* relative to
 18 salinity, turbidity, particulate organic carbon (POC), chlorophyll *a* (Chl. *a*), phaeopigments (Pheo.)
 19 and POC:Chl. *a* ratios in the Chikugo River estuary from March 2005 to December 2006. $\Delta\delta^{13}\text{C}$
 20 values were calculated by subtracting $\delta^{13}\text{C}$ in POC from $\delta^{13}\text{C}$ in copepods at each station on each
 21 sampling date. Significant coefficients are indicated by asterisks.

	Salinity	Turbidity	POC	Chl. <i>a</i>	Pheo.	POC:Chl. <i>a</i>
$\Delta\delta^{13}\text{C}$ in <i>S. sinensis</i>	0.29*	-0.02	-0.24	-0.02	-0.33*	-0.12
$\Delta\delta^{13}\text{C}$ in <i>P. inopinus</i>	0.27	-0.28*	-0.61*	-0.09	-0.60*	-0.35*
